## ACKNOWLEDGEMENT

*“In the name of Allah, The Most Gracious and The Most Merciful”*

All praise belongs to Almighty Allah (s.w.t.) for bestowing me with courage and perseverance to carry out this work sincerely. I thank Almighty Allah for giving me chance to do my M.S. successfully at King Fahd University of Petroleum and Minerals, Dhahran. I am happy to have had a chance to glorify His name in the sincerest way through this small accomplishment and ask Him to accept my efforts.

Acknowledgement is due to King Fahd University of Petroleum and Minerals for providing me financial support and good academic environment during the course of my M.S. Special thanks is also due to the Center of Clean Water and Clean Energy at M.I.T and KFUPM.

My deep gratitude and appreciation goes to my thesis advisor, my mentor Dr. Hassan M Badr for his constant endeavor, guidance and motivation during the course of my study. His valuable and priceless suggestions made this work interesting and challenging for me. I also wish to express my deep appreciation to Dr. M A Habib for his help, guidance, and constant encouragement during my M.S. I am greatly indebted to Dr. Rached Ben Mansour for the valuable time he spent throughout my thesis work and also for always being supportive and helping me during difficult times.

I would also like to acknowledge all the Mechanical Engineering faculty members with whom I took courses during my M.S. especially Dr. Shuja and Dr. Yilbas who helped me a lot, guided me and encouraged me during my coursework and related research.

## THESIS ABSTRACT (ENGLISH)

**NAME:** AHARUDDIN

**TITLE:** PERFORMANCE ANALYSIS OF OXYGEN TRANSPORT REACTOR  
UTILIZING ION TRANSPORT MEMBRANES

**MAJOR:** MECHANICAL ENGINEERING

**DATE:** DEC 2011

*This study aims at investigating the performance of a cylindrical ion transport reactor designed for oxy-fuel combustion. The cylindrical reactor walls are made of dense, nonporous, mixed-conducting ceramic membranes that only allow oxygen permeation from the outside air into the combustion chamber. The sweep gas ( $\text{CO}_2$  and  $\text{CH}_4$ ) enters the reactor from one side, mixes with the oxygen permeate and the combustion products are discharged from the other side. The process of oxygen permeation through the reactor walls is influenced by the flow condition and composition of air at the feed side (inlet air side) and the gas mixture at the permeate side (sweep gas side). The modeling of the flow process is based on the numerical solution of the conservation equations of mass, momentum, energy and species in the axi-symmetric flow domain. The membrane is modeled as a selective layer in which the oxygen permeation depends on the prevailing temperatures as well as the oxygen partial pressure at both sides of the membrane. The CFD calculations were carried out using FLUENT 12.1 while the mass transfer of oxygen through the membrane is modeled by a set of user defined functions. The model*

*results were validated against previous experimental data and the comparison showed a good agreement. Further, the study is carried out for the optimal composition mixture of sweep gas for cold-combustion (mixing) within the reactor. Lastly the integration of membrane model with ITM reactor as combustion chamber is done by using single step methane combustion chemistry. The results showed the significant increase of  $O_2$  permeation in case of combustion in comparison with cold combustion.*

## THESIS ABSTRACT (ARABIC)

الاسم: اظهر الدين

العنوان: تحليل اداء مفاعلات نقل الأكسجين باستخدام الاغشية الناقله الايونيه  
التخصص: الهندسة الميكانيكية .

التاريخ: ديسمبر 2011 .

تهدف هذه الدراسة إلى التحقيق في أداء مفاعل نقل ايوني أسطواني مصمم لاحتراق الوقود مع الأكسجين . تم اعتبار جدران المفاعل الاسطواني المصنوع من ماده غير مسامية من السيراميك ناقلة للأيونات والإلكترونات وتسمح فقط للأكسجين للتغلغل من الهواء الخارجي لغرفة الاحتراق . يدخل غاز الاكتساح (خليط من ثاني أكسيد الكربون وغاز الميثان) إلى المفاعل من جانب واحد، يختلط مع الأوكسجين ويتم تفريغه من نواتج الاحتراق من الجانب الآخر. تتأثر عملية تغلغل الأكسجين من خلال جدران المفاعل بحالة تدفق وتكوين الهواء في جانب التغذية. (مدخل الهواء الجانبي)، وخليط الغاز في الجانب الآخر من الغشاء (جانب غاز الاكتساح). ويستند وضع نماذج عملية التدفق على الحل العددي لمعادلات حفظ الكتلة والطاقة والحركة ومكونات الغاز . وتم تصميم ونمذجة الغشاء كطبقة انتقائية يعتمد فيها تغلغل الأكسجين على درجات حرارة الغشاء بالإضافة إلى الضغط الجزئي للأكسجين في جانبي الغشاء. وأجريت عمليات توازن الموائع الحسابية CFD باستخدام برنامج FLUENT 12.1 في حين يتبع انتقال كتلة الأكسجين من خلال الغشاء نمودجا خاصا تم تطويره في هذا البحث. تم التحقق من صحة نتائج النمودج بالمقارن مع بيانات تجريبية سابقة وأظهرت المقارنة اتفاقا جيدا مع النتائج. علاوة على ذلك، أجريت الدراسة لتكوين الخليط الأمثل لغاز الاكتساح من أجل الاحتراق البارد (الخلط) داخل المفاعل. وأخيرا تم دمج نمودج الغشاء مع مفاعل غشاء النقل الأيوني ( ITM ) كغرفة احتراق عن طريق استخدام احتراق غاز الميثان كيميائيا مباشرة إلى نواتج الحريق بخطوه واحده. واطهرت النتائج ان هناك زيادة كبيرة في تغلغل الأكسجين في حالة الاحتراق مقارنة مع الاحتراق البارد (الخلط).

# CHAPTER 1

## INTRODUCTION

### 1.1 Research Background

Most of the energy used worldwide is derived from fossil fuels. Combustion of fossil fuels leads to emissions of CO<sub>2</sub> into the atmosphere, which is known to contribute to the undesired global warming. It is generally accepted that the increase in the temperature of the earth is linked to the increase in greenhouse gases, mostly CO<sub>2</sub>, in the atmosphere. Saudi Arabia has ratified the Kyoto protocol [1], which sets strict limits on emissions of CO<sub>2</sub> and imposes penalties.

CO<sub>2</sub> is a major greenhouse gas released whenever fuels containing hydrocarbon, such as methane, are burned. Most of the world's energy needs are currently met by combustion of hydrocarbon fuels. Renewable energies are carbon neutral and present a favourable solution to the problem of greenhouse gas emissions. Unfortunately renewable energy technologies are currently not mature enough in comparison to fossil fuel based technologies. Much work is required before such energy sources will produce a major portion of our energy. Another method of power production is nuclear technology that does not contribute to the global warming problem. However acceptance of nuclear power by the public is quite low, particularly in Saudi Arabia.

Fossil fuels are heavily used in power industry as it is relatively cheap and abundant. The Hubbert oil peak is the maximum production of oil. In theory it coincides with the midpoint of the available oil in a region. Various current estimates place the world peak between 2009 and 2035 [2], implying that there is at least as much oil still available in the world as has been consumed since the industrial revolution. The discovery of methane hydrates in vast quantities indicates that fossil fuel will continue to be used for decades to come. Unfortunately combustion of these fuels produces pollutants and CO<sub>2</sub>, the main contributor to global warming. One of the main challenge facing engineers now is how to reduce or prevent the negative impact of CO<sub>2</sub> on the climate caused from power plants, while allowing the continued use of fossil fuels for power production.

Carbon capture and sequestration (CCS) means capturing CO<sub>2</sub> and trapping it away from the atmosphere. There are many methods of sequestering CO<sub>2</sub> either by utilization in industrial processes or by storage underground or in deep seas. Enhanced Oil Recovery (EOR) is another option which involves injecting CO<sub>2</sub> into partially depleted oil wells to increase oil production. This is currently common practice in many oil companies. Over 40 Million cubic feet of CO<sub>2</sub> can be injected daily into oil well in Ghawar, Saudi Arabia by 2012 which was reported by Minister of Petroleum, Saudi Arabia [3].

CO<sub>2</sub> is also utilized in Enhanced Coal Bed Methane Recovery (ECBM) for harvesting methane from unmineable coal by injecting CO<sub>2</sub> into the coal bed. The neutralization of

alkali pollutants can be done by using CO<sub>2</sub> in polluted areas. Yet another method is to absorb CO<sub>2</sub> into coal beds that are inaccessible and cannot be mined. Some minerals will react with CO<sub>2</sub> to form a solid product. There are two methods of doing this; the first is mining the reactant mineral and the second is reacting it with CO<sub>2</sub> to produce a product which can be used in road pavement, or injecting CO<sub>2</sub> into subterranean caverns containing the reactant mineral, and allowing it to slowly react over time. Other methods of CO<sub>2</sub> storage include injection into some geological formations, particularly porous rock. Calculation of storage capacity can be done of various types of geological formation. Akinfiyev et al [4] presented theoretical calculations for formation of methane by a reaction of CO<sub>2</sub> with Fayalite, an abundant mineral, and discussed the possibility of a closed carbon cycle. In effect, Fayalite becomes a fuel, with methane being the energy carrier, and no emissions to the atmosphere. Many studies are being undertaken on sequestration, and many numerical simulations have been developed and tested [5, 6].

Until now many methods have been proposed for capturing CO<sub>2</sub> produced by combustion of fossil fuels for production of electricity. The fuel may be burned in air, and the exhaust products separated to capture CO<sub>2</sub>. This usually involves either cryogenic or chemical processes, or use of membranes to separate gases. These methods are costly and consume a large amount of energy, thus resulting in reducing the power plant efficiency. Alternatively, carbon may be removed from hydrocarbon fuel before combustion, for example by conversion of methane to syngas, a mixture of carbon monoxide (CO) and hydrogen (H<sub>2</sub>), followed by separation of H<sub>2</sub> from the mixture. It is possible to produce

pure  $H_2$  by this method, so that the  $H_2$ -using technology is emission free. However it is difficult to separate CO from  $H_2$  as both are gases and the remaining CO will contain some unseparated  $H_2$ . This mixture is also an energy rich fuel source, and  $CO_2$  will be produced by burning this CO-rich syngas. Another method is to use  $O_2$  only instead of air for combustion which gives  $CO_2$  and  $H_2O$  as flue gases and by condensation process  $H_2O$  can be easily separated and  $CO_2$  can be sequestrated as discussed in this section. Separation of  $O_2$  from air takes large amount of energy by conventional air separation technology. The other alternative to separate  $O_2$  from air is use to Ion Transport Membranes (ITM) by which power loss is very low compared to cryogenic methods. In the present work, the use of ITM in order to separate  $O_2$  and its integration as combustion chamber is studied which can retrofit the conventional gas turbine combustion chamber to ITM reactor. This concept utilizes a high temperature mixed ionic and electronic conducting ceramic membrane to separate  $O_2$  from air and in some cases concurrently oxidizes the fuel within the same reactor which can reduce the size and can enhance the oxygen separation. However, many implications and operational constraints imposed by using ITMs within a power cycle still need to be addressed, and the thermodynamic penalty must be assessed before the benefits of ITM technology can be realized. In order to study whether or not these systems can fit into present power cycles numerical simulation is a good approach. Numerical solution of this kind of reactor can help to understand the feasibility of using this technology in power cycles.

## **1.2 Problem Statement**

The problem considered in this work is that of an oxygen transport reactor of cylindrical shape in which a mixture of  $\text{CH}_4$  and  $\text{CO}_2$  (sweep gas) are injected from one side and the oxygen permeates through the ITM walls of the combustor. The combustion products are discharged through the other end of the combustor. The study will focus on the following:

1. Investigating the effect of the oxygen partial pressure in the air side on the oxygen permeation rate through the ITM and validation of the computational model against the experimental data available in the literature.
2. Studying the effect of con-current and counter-current flows of sweep gas on oxygen permeation for cold combustion
3. Investigating the effect of the sweep gas composition on the oxygen permeation rate through the ITM and the size and geometry of the resulting combustion zone.
4. Investigating the effect of combustion in the oxygen transport reactor and the effect of oxygen permeation rate through the ITM.

## **1.3 Objectives**

The objectives of the thesis are listed below:

1. To develop a model for permeation of oxygen through Ion Transport Membrane (ITM) by creating source and sink terms at the membrane boundary cells in the continuity and species transport equation.
2. Validation of the model developed using experimental data from the literature.
3. To study the influence of partial pressure and gas temperature on oxygen permeation through the ITM.
4. To study the effect of con-current and counter-current flows of sweep gas on oxygen permeation.
5. To simulate the combustor of an oxygen transport reactor on a cold-combustion basis and to study the influence of the  $\text{CO}_2/\text{CH}_4$  ratio on oxygen permeation rate from rich to lean mixtures.
6. To simulate the oxygen transport reactor for combustion with one step reaction with methane and to study the influence of  $\text{CO}_2/\text{CH}_4$  ratio on  $\text{O}_2$  permeation and to determine the amount of methane required for the present combustor.

#### **1.4 Thesis Outline**

This thesis contains six chapters.

Chapter 1 introduces the subject of Carbon capture and Sequestration and importance of Oxy-fuel combustion to mitigate greenhouse gases specially  $\text{CO}_2$ . The utilization of  $\text{CO}_2$

in various industrial processes is also presented. The problem statement and objectives of the present thesis are discussed.

Chapter 2 is mainly a literature review and is divided in four sections. First section is about carbon capture methods and the second section focuses on oxyfuel combustion in power cycles. The third section is about the membrane separation technologies used for these CO<sub>2</sub> capture operations and viability of these systems in power cycles. The last section highlights the numerical schemes that were applied by previous researcher for separation technologies.

In Chapter 3, a membrane permeation model has been developed in order to study separation of O<sub>2</sub> from air by using different compositions of inert sweep gas. It also explains the combustion methodology that has been adopted (single step chemistry) to create the reducing environment when fuel is used as sweep gas.

In Chapter 4 the numerical method used for solving the flow, species transport and combustion processes is discussed. The results of grid independence test and validation of the C.F.D code are presented.

Chapter 5 is divided into two sections. The first section focuses on discussion of results in the case of cold combustion and the second section focuses on discussing the results in the case of combustion.

In Chapter 6, the conclusions of this study are presented. The recommendations of possible future research in this area also presented.

# CHAPTER 2

## LITERATURE REVIEW

The literature review presented in this chapter is divided into four sections. The first section presents the research done in carbon capture and sequestration technologies and the attempt of changing from air-fuel combustion to oxyfuel combustion in power generation systems and the economic viability of these systems. In the second section, the research work accomplished to use the oxyfuel process in power cycles. In the third section, the research carried to develop alternatives to replace the air separation unit by membrane reactors which save a good amount of power. The last section of this chapter presents the numerical work carried out to model separation of species from a mixture of gases.

### **2.1 Carbon Capture and Sequestration technologies**

The statement given by IPCC [7]: 'Emissions of CO<sub>2</sub> due to fossil fuel burning are virtually certain to be the dominant influence of the trends in atmospheric CO<sub>2</sub> concentration during the 21st century'. CO<sub>2</sub> is considered to be the greenhouse gas that makes the largest contribution from human activities. With the on-going debate on global warming and climate changes there is a clear incentive to investigate strategies to reduce the emissions of CO<sub>2</sub> to the atmosphere. One way to achieve this is to remove CO<sub>2</sub> from

exhaust gases from the power plants and store it away from the atmosphere, i.e. CO<sub>2</sub>-capture and sequestration.

Figure 1 World Energy consumption based on usage based on the types of fuel (Mtoe) [8]

Figure 2 World CO<sub>2</sub> emissions from different types of fuels (Mt of CO<sub>2</sub>) [8]

Figure 1 show how the world energy is produced in the last few decades [8]. As most of the energy is produced from fossil fuels, this also causes an increase in CO<sub>2</sub> emissions which can be seen clearly in Figure.2. According to IPCC [9], the average yearly growth

in CO<sub>2</sub> emissions during the period 1995-2001 was 1.4%, a number that was higher than the five year period before that.

In this thesis, CO<sub>2</sub>-capture and storage will be referred to as CCS. When considering combustion of fossil fuels, it is required to separate CO<sub>2</sub> from flue gases and store it somewhere away from the atmosphere. While capture of CO<sub>2</sub> is possible for all types of combustion, it is only considered to be viable for large power (or industrial) plants. Capture of CO<sub>2</sub> from, for instance, an automobile engine would be very expensive, and it would also be a major problem to gather all the captured CO<sub>2</sub> and store it. Figure 3 shows four different concepts to achieve CO<sub>2</sub> capture. One is an industrial plant where CO<sub>2</sub> is separated from the flue gases in the process. The other examples are power plants, for which there are three different approaches for carbon capture; post-combustion, pre-combustion and oxy-fuel. These approaches will be discussed in more detail below. The common process in all of these approaches is the handling of the captured CO<sub>2</sub>. For transportation of CO<sub>2</sub>, it should be compressed and possibly liquefied to reduce its volume. Several options are available as storage sites, but only deep ocean and large geological formations are considered to be large enough to handle the required quantities. Depleted oil and gas fields have been suggested as a promising storage place as discussed in the introduction. Oil wells are already drilled, and equipped for injection to the underground, thus become appropriate sites for CO<sub>2</sub> sequestration. Another advantage of CO<sub>2</sub> injection in oil wells is its usage in enhancing oil recovery.

Figure 3 CO<sub>2</sub> capture system [9]

### 2.1.1 Pre-combustion capture:

Decarbonisation of fuel gas is done in pre-combustion systems. In chemical and refining industries, this process has been used for hydrogen production for more than five decades [10]. In this type of systems, the primary fuel is processed in a reactor in the presence of steam and air (or oxygen) to produce a mixture consisting mainly of carbon monoxide and hydrogen (synthesis gas). The reaction between the carbon monoxide with steam in a second reactor (a “shift reactor”) produces additional hydrogen and CO<sub>2</sub>. The resulting

mixture of hydrogen and  $\text{CO}_2$  can then be separated into a  $\text{CO}_2$  gas stream, and a stream of hydrogen. If  $\text{CO}_2$  is stored, the remaining hydrogen is a carbon-free energy carrier that can be combusted to generate power and/or heat with no  $\text{CO}_2$ . Although the initial fuel conversion steps are more elaborate and costly than that of post-combustion systems which is discussed in later sub-section, the high concentrations of  $\text{CO}_2$  produced by the shift reactor (typically 15 to 60% by volume on a dry basis) and the high pressures often encountered in these applications are more favourable for  $\text{CO}_2$  separation. Pre-combustion can be used in natural gas or coal based plants that employ integrated gasification combined cycle (IGCC) technology as can be seen in Figure 4.

Figure 4 Pre-combustion process [9]

### 2.1.2 Post combustion capture:

It involves separation of  $\text{CO}_2$  from the flue gases produced by the combustion of the primary fuel in air. These carbon capture systems normally use a liquid solvent mostly

amines- to capture the fraction of CO<sub>2</sub> present in the flue gas stream by a chemical reaction. The flue gas must contain very low levels of oxides of nitrogen and sulphur (NO<sub>x</sub> and SO<sub>2</sub>) to form stable, non-regenerable salts in reaction with the amine. This means that post-combustion CO<sub>2</sub> capture on coal fired power plants requires upstream de-NO<sub>x</sub> and flue gas desulphurization (FGD) facilities. The solvent is then regenerated.

For a modern pulverized coal (PC) power plant or a natural gas combined cycle (NGCC) power plant, current post-combustion capture systems would typically employ an organic solvent such as monoethanolamine (MEA) [9, 10, 11, 12].

The requirement of heat for the current generation of solvents is high and has a major impact on the overall efficiency of the power plant since steam which would otherwise generate power in the LP turbine of the plant is now used to regenerate the solvent instead. Integration of the heat cycle of plants fitted with post-combustion capture is essential to minimise the impact of the capture process on the overall plant efficiency [13].

### **2.1.3 Oxyfuel Combustion:**

Oxyfuel combustion systems use oxygen instead of air for combustion of the primary fuel to produce a flue gas that is mainly consisting of water vapour and CO<sub>2</sub>. Normally, the flue gas has high CO<sub>2</sub> concentrations and by cooling and compressing the gas stream, water vapour can be removed easily. It may have potential as a part of a system for

capturing and storing  $\text{CO}_2$  as the nitrogen concentration in the flue gas is much lower than that in case of using air for combustion. So, the  $\text{CO}_2$  can be stored with less downstream processing. Oxyfuel combustion systems are, in principle, able to capture nearly all of the  $\text{CO}_2$  produced. However, the need for additional gas treatment systems to remove pollutants such as sulphur and nitrogen oxides lowers the level of  $\text{CO}_2$  captured to slightly more than 90%. The most widely considered technology for oxygen production is cryogenic air separation. The auxiliary power consumption of a cryogenic air separation unit is high and has a major impact on the overall efficiency of the power plant. Further treatment of the flue gas may be needed to remove air pollutants and non-condensed gases (such as nitrogen) from the flue gas. As a method of  $\text{CO}_2$  capture in boilers, Oxyfuel combustion systems are in the demonstration phase. Oxyfuel systems are also being studied in gas turbine systems, but conceptual designs for such applications are still in the research phase [9] and the related flow diagram can be seen in Figure 5. Integration of the thermodynamic cycle of plants fitted with Oxyfuel capture is essential to minimise the impact of the capture process on the overall plant efficiency.

Figure 5 Oxyfuel Process [9]

Among all capture methods, CO<sub>2</sub> scrubbing techniques are the most mature. MEA-based scrubbing has been utilised for more than 60 years for natural gas purification and food-grade CO<sub>2</sub> production. In particular, Rectisol and Selexol processes have been commercially used since the 1990s for CO<sub>2</sub> capture in the refining, chemical and fertilizer industries and are today extensively used in gasification plants to purify synthesis gas for downstream chemical applications. Current units, using these techniques, are able to remove thousands of tonnes of CO<sub>2</sub> per day [14]. However, they have not yet been demonstrated on the large scale necessary for 90% CO<sub>2</sub> capture from a typical 500MW coal fired power plant where 10000–15000 tons of CO<sub>2</sub> would be removed per day.

Other capture technologies such as anti-sublimation, enzymes and algae for post-combustion and chemical looping and high pressure oxy-reactor are still at an early stage of development, with commercial deployment generally considered to be unlikely before 2025.

#### **2.1.4 Economic viability:**

The study of economic viability of these technologies is an important issue that has to be considered. Since the coal fired power plants generate high rate of flue gases but with low CO<sub>2</sub> concentration. There is huge capital investment needed to install the post combustion systems for massive volumes of flue gases in the present conventional power generation systems. Since most of the processes for CO<sub>2</sub> capture is energy intensive, pre-combustion or oxyfuel processes are viable processes which lies within low investment.

The Air Separation units (ASU) which uses cryogenic process to separate of oxygen and nitrogen may alone consume about 13% of the power plant output [15]. On the other hand gas separation membranes have relatively low energy consumption and their integration into membrane reactors is very promising. Therefore, they are excellent for gas separation in retrofitting coal-fired power plants and the oxyfuel combustion power plant.

## **2.2 Oxyfuel combustion in power cycles**

In his paper, Kvamsdal et al [16] reported a comparison of power plant overall efficiency utilizing different CO<sub>2</sub> capture techniques with that of conventional power plant with no CO<sub>2</sub> capture as shown in Figure 6. The figure indicates a maximum efficiency of 57% for conventional power plant with no CO<sub>2</sub> capture. It can be seen that technology progresses towards 100% CO<sub>2</sub> capture with higher efficiency. Out of many cycles shown, Advanced Zero Emission Process (AZEP) cycle showed maximum carbon capture with very low efficiency penalty. It 85% CO<sub>2</sub> capture the efficiency penalty was 4% compare with no CO<sub>2</sub> capture and with 100% CO<sub>2</sub> capture it was 7% . From the technical side, the oxyfuel process can be applied to the existing coal-fired power plants and we can build new one with only oxyfuel combustion chambers [17]. The new technology of membrane separation and combustion is not yet fully matured to commercialize to manufacture a large scale power production unit.

Figure 6 various technology showing efficiencies [16].

However, the efforts put by the researchers [18, 19, 20, 21, 22] show great potential to implement this membrane integration with oxy-rich fuel combustion. Several aspects of oxyfuel processes for use in coal-fired power plant are currently under investigation, e.g. boiler design, combustion reactions and chemistry of combustion, sealing issues for Oxygen Transport Reactor (OTR) in order to make this technology more viable. Vattenfall a Sweden based company has commissioned the world's first coal-fired plant with CO<sub>2</sub> capture technology in September 2008 with a thermal capacity of 30 MW [23]. The idea of this oxyfuel combustion can be extended to natural gas combustion with membrane integration in a combustion chamber. More work has to be done for

clarification of combustion issues such as reaction kinetics, ignition (in case of coal-fired), flame stability, sealing of membrane and the activation energy required for operating these OTR.

### **2.2.1 Combustion in power cycle**

The combustion oxidizer generally used for oxyfuel processes should have a purity of more than 95% and the rest being nitrogen [24, 25]. In coal-fired combustion there must be excess oxygen supplied to the boiler which is necessary to obtain a stoichiometric and homogenous combustion. In the flue gas, there will be CO<sub>2</sub> along with H<sub>2</sub>O vapours with small concentration of NO<sub>x</sub>, SO<sub>x</sub>, etc. The boiler flue gas is sent to a clean-up process to remove acid gases and particulates. Then it is again treated for NO<sub>x</sub> removal in deNO<sub>x</sub> treatment unit, this NO<sub>x</sub> generation due to the air-leakage in boiler which accounts to 8%-15% [24]. SO<sub>x</sub> treatment is also necessary for the removal of sulphur inside the boiler [26, 27]. After complete dehumidification of the flue gas, it is estimated that the purity of remaining CO<sub>2</sub> ranging 85% to 95% [18, 28, 11] and is ready for compression and storage.

If the combustion is done with natural gas (mainly methane) in an oxygen transport reactor then the process of DeNO<sub>x</sub> and DeSO<sub>x</sub> treatment can be avoided since with membranes supply very high purity of oxygen and the leakage is also negligible compared to boiler furnace. Since the oxygen flames give higher temperatures that should be controlled, around 2/3 of the flue gas need to be recycled [17]. The missing element of N<sub>2</sub> is replaced by recycled CO<sub>2</sub> which will carry away the heat and will increase the

concentration of CO<sub>2</sub> [27]. Moreover, the recycled CO<sub>2</sub> is used to sweep out the permeate side of the membrane thus lowering the oxygen partial pressure and allowing the required gradient of O<sub>2</sub> partial pressure across the membrane.

### **2.2.2 Flue Gas Composition:**

The work done by Kakaras et al [25] for lignite fired power plant with oxyfuel boiler shows a composition of 66% of CO<sub>2</sub> by weight and 19% of H<sub>2</sub>O and N<sub>2</sub> and Ar of 8% and O<sub>2</sub> is 1% at boiler exit. The emission analysis done by Fabienne et al [26] for a small lab scale plant with a capacity of 1.5 MW showed flue gas composition of 80% CO<sub>2</sub>, 17% N<sub>2</sub>, and 3% of O<sub>2</sub>. The study done by Singh et al [11] indicated that for the 400 MW pulverised coal-fired power plant, the dry flue gas composition was 91% CO<sub>2</sub>, and 75% CO<sub>2</sub> on wet basis. These studies showed that the ideal O<sub>2</sub> to CO<sub>2</sub> ratio in the feed is 30/70 with around 50% recycled flue gas which will lead to CO<sub>2</sub> purity of more than 97% [21, 22, 27].

In general oxyfuel combustion process in which oxygen is separated and feed to the combustion chamber, is considering two mechanisms for the flue gas recirculation. The first mechanism is called “wet recycling”, the flue gas is recycled directly after clean-up processes removes particulates and acid gases. The swept gas will be mainly composed of water and CO<sub>2</sub>. The second mechanism is “dry recycling” in which water is removed from the flue gas by condensation. This condensation doesn’t remove all water but after condensation the flue gas passes through molecular sieves to eliminate the water completely [28]. The schematics of the two mechanisms are shown in Figure 7 and 8.

In case of Oxygen transport reactor in which  $O_2$  permeation and combustion takes place at the same time, the recycled  $CO_2$  will play a major role in controlling the temperature of the reactor and increasing the  $CO_2$  concentration at the exit of the combustor.

Figure 7 Oxyfuel process with water condensation [25]

Figure 8 Oxyfuel process without water condensation [28]

### 2.2.3 Oxyfired power plants incorporating oxygen transport membranes (OTM):

A number of configurations are designed and some are installed while others are under laboratory testing. In 2005, the world's first oxyfired power plant was installed in Kamberlina, California, USA by Clean Energy Systems (CES) [29].

As stated earlier, the cryogenic air separation is accompanied by huge loss of efficiency of oxyfired cycles. The air separation with cryogenics requires air compressing and then cooling to very low temperature of about  $-183^{\circ}\text{C}$  which liquefies oxygen for separation from nitrogen. The liquefied oxygen is then heated and used in oxyfired cycles; the whole process accounts of 13% loss of efficiency [15]. However, OTMs offers oxygen production without high adverse effect on efficiency. Oxygen transport Membranes have been incorporated in power cycles and a well-developed example is Advanced Zero Emission Power (AZEP) cycle [30] as shown in Figure 9. In this cycle, air after being compressed, it is split into two parts. The first of is used to heat steam and air, while the other part is mixed with oxygen in OTM unit which is sometimes called as Mixed Conducting Membrane reactor (MCM) in the figure 9 and returns to the combustion chamber as oxidant. The membrane conducts oxygen to the fuel side and heats the air side. The membrane doesn't have to withstand flames since combustion occurs away from the membrane wall, but hot combustion products enters the OTM reactor at temperature close to adiabatic combustion temperature. The oxygen depleted turbine (main turbine) drives both air compressor and the electrical generator. The combustion products are used to heat the working fluid in the Rankine cycle and are then cooled to condense  $\text{H}_2\text{O}$  after boiler leaving only  $\text{CO}_2$ . The thermal efficiency of AZEP cycle was is compared with conventional combined cycle power plant and it was found to be about 8.3% lower [31].

This efficiency loss is mainly due to the reduced inlet turbine temperature which was about 1200 °C and it causes significant amount of power loss both in steam and gas turbine. The efficiency of the cycle was claimed to increase, by increasing the inlet turbine temperature which can be done by additional fuel firing in the heated air stream before the gas turbine, from 50% to 54% [31] but with a penalty of CO<sub>2</sub> capture which was about 8.5%. The other cycle which was developed with OTM is Oxycoal-AC cycle in Germany. By the name suggests pulverised coal is used as fuel. The combustion products provide heat to air stream and bottoming Rankine cycle. In this cycle, air turbine drives the compressor and the power is generated in bottoming cycle only. The efficiency of the cycle was reported 41.6% with 4-end concept and 39.7% with 3-end concept [32]. The 4-end concept and 3-end concept is described in the next paragraph and shown in Figure 10 and 11.

Stadler et al [33] carried out research on oxyfuel coal combustion by efficient integration of Oxygen Transport Membranes for possible implementations of OTM into an Oxyfuel process through three-end and four-end integration of membranes. He focused on the overall cycle efficiency for different level of integration which includes low, medium, high integration, high integration with fogging and Co-firing. The four-end concept refers to the application of sweep stream on the low pressure side in order to remove the permeating component and thereby increasing the driving potential whereas in the three-end concept vacuum is applied at the permeate side and can be seen figure 12.

Figure 9 AZEP Oxyfired cycle incorporating OTM [30]

The OTM materials used in the analysis was BSCF. The operating temperature of the membrane was about 825°C and the mean oxygen partial pressure ratio was in between 3 and 26. The oxygen flux across the membrane is determined by the following Wagner-equation

$$J_{O_2} = \frac{C_{wagner} T_{membrane}}{d} \exp\left(\frac{-K_{wagner}}{T_{membrane}}\right) \ln\left(\frac{p_{O_2, feed}}{p_{O_2, permeate}}\right)$$

where  $C_{wagner}$  and  $K_{wagner}$  are membrane material properties and constants which can be determined experimentally.

- Recirculation fan 7. Flue gas cleaning 8. CO<sub>2</sub> conditioning.

Figure 12 Oxygen Conduction in OTM in four-end design (left) and three-end design (right)

It's was expected that the efficiency can be improved through optimisation of membrane operation parameters such as oxygen separation degree, the partial pressure ratio and the total pressure ratio. It was found from the analysis that the oxygen concentration varies linearly with the separation degree and with 90% separation degree, 16.5 vol% concentration of oxygen and with the partial pressure ratio of 26 the adiabatic flame temperature achieved was about 1500°C. The analysis gives quite evidence of the four-end design got more capability of producing high efficiency than three-end design shown in figure 12. The critical remarks found are the membrane material stability at high elevated temperatures and permeability of the membranes which affects the overall efficiency of the plant.

The concept developed by E Yantovski [34] for oxyfired power plant with zero emission resulted in a new cycle called ZEITMOP (Zero Emission Ion Transport Membrane Oxygen Power) cycle. This cycle is shown in Figure 13 and was developed to work on all type of fossil fuels. The cycle has three turbines, one for combustion products, second for depleted oxygen and third for CO<sub>2</sub> recirculation through the system.

Figure 13 The ZEITMOP cycle in which OTR is remote from Combustion chamber [33]

Methane (1) is compressed in compressor A (2) and burned in combustion chamber B in a mixture of O<sub>2</sub> and CO<sub>2</sub> (17). The exhaust products (3) are expanded in turbine C (4) and are then cooled in two heat exchangers D and E (5,6) before being further cooled in cooling tower F (7), causing the water in the combustion products to condense. The liquid water is separated in water separator G and removed (18) leaving almost pure CO<sub>2</sub> (8). The CO<sub>2</sub> is compressed in a three stage compressor H with intercooling in the cooling

tower F to 210 bar (9-13) and the portion born of combustion is captured (19). The rest of the CO<sub>2</sub> (14) is heated in heat exchanger E (15) and expanded in turbine I (16) before entering the OTM unit J where it is mixed with O<sub>2</sub> (25), then returns to combustion chamber B (17). Air (20) is compressed in compressor K (21) and heated in heat exchanger D (22) before entering OTM unit J in which the O<sub>2</sub> required for combustion (25) is separated. The hot depleted oxygen air is expanded in a turbine L (23) before it is being discharged to atmosphere. The water and CO<sub>2</sub> produced from combustion was in liquid phase hence they are considered as effluents, not emissions. The water can be removed totally in separator G and CO<sub>2</sub> is captured and sequestered.

The approximate pressure and temperature obtained in the range 15 to 40 bar and 800 to 900°C for oxygen separation through dense, nonporous, mixed-conducting ceramic membranes. The paper shows how the efficiency varies with different cycle selection and implementation of ITMs. To show the feasibility of ITMs, the numerical analysis of ZEITMOP power cycle with separate combustion and ITM reactor was done [33]. The economic issue such as cost of manufacturing membranes and oxygen flux at 900 °C were discussed. For the combustion temperature range of 1000-1400 °C, thermal efficiency obtained between is in the range of 46%-52% with CO<sub>2</sub> circulation.

Foy [35] carried out a computational analysis for the combined OTR and combustion chamber in ZEITMOP cycle as shown in Figure 14. The ZEITMOP-Combined cycle was simulated at a combustion pressure of 15 bar and combustion temperatures of 1000°C (which would be the likely maximum combustion temperature if perovskite membranes

were used) and  $1400^{\circ}\text{C}$ . It is similar to the previous cycle but the average working temperature in which OTR was changed with separate module and combined module of OTR. The combined ZEITMOP cycles showed a realistic behaviour and more work is needed to optimise the cycle efficiency and parameters that involve the design of OTR to work at high temperature with controlled combustion. Tzimas et al [36] investigated the impact of  $\text{CO}_2$  capture in fossil fuel power plants on the emissions of nitrogen oxides ( $\text{NO}_x$ ) and sulphur oxides ( $\text{SO}_x$ ). This was done by estimating the emissions of these chemical compounds from natural gas combined cycle and pulverized coal plants, equipped with post-combustion carbon capture technology for the removal of  $\text{CO}_2$  from flue gases, and comparing them with the emissions of similar plants without  $\text{CO}_2$  capture.

It was indicated that the  $\text{NO}_x$  emissions from the power generation sector are likely to increase when carbon capture technologies are implemented on a large scale, due to the reduced efficiency of such power plants.

For optimizing the thermal efficiency of the cycle, many formats can be selected for  $\text{CO}_2$  capture and improving the working performance of OTR. This has very wide potential in making hybrid power plants with OTR for carbon capture and integrating with the renewable energy sources like solar. Foy's [35] work was focused on the study of combustion chamber with OTR and the result can be used to optimise the total cycle efficiency. From the above discussion it was found that there is potential in changing the technology from air-fuel to oxy-fuel is worth and that needs more research to address the problems in implementing the change.

Figure 14 The ZEITMOP cycle with OTR and combustion chamber combined [35]

### 2.3 Membranes for gas separation in Carbon capture and sequestration

Generally there are three types of membranes currently available for gas separation applications and are considered for CO<sub>2</sub> capture:

- Organic porous polymer membranes.
- Inorganic porous membranes, amorphous or crystalline
- Inorganic dense membranes, metallic or ceramic

Organic polymeric membranes are excellent candidate for CO<sub>2</sub> separation from N<sub>2</sub> for the post-combustion process. These membranes can even separate the H<sub>2</sub>/CO<sub>2</sub> in pre-combustion process but they have low thermal stability and not suitable for high

temperature and pressure applications [37]. On the other hand dense inorganic membranes are suitable for  $\text{H}_2/\text{CO}_2$  and  $\text{O}_2/\text{N}_2$  separation.

#### **2.3.1 Mixed Ionic and Electronic Conducting (MIEC) Membranes for $\text{O}_2/\text{N}_2$ separation:**

MIEC membranes have been tested for oxygen separation from air and regarded as clean, cost effective technology. These membranes are dense in nature with no detectable pores which means that the oxygen molecules cannot pass through these membranes. These membranes have the capability of separating oxygen from air because of the oxygen vacancies in the crystal lattice which is created by doping of the material. Oxygen ions are transported from one side of the membrane to the other by a mechanism called hopping. This mechanism is activated only if the oxygen anions have enough thermal energy to overcome the energy barrier to hop from one side of the crystal lattice to the other which means that the membrane are operable at high temperatures. The typical range for the membranes to activate the mechanism of oxygen transport is  $700^\circ\text{C}$  to  $1000^\circ\text{C}$  [38]. There will be a counter-balancing electron transport to maintain electro-neutrality in the material and there is no need of any potential voltage for the oxygen transport.

#### **2.3.2 Oxygen Transport Theory:**

In ITM membranes, the oxygen transport occurs because of the partial pressure difference across the membranes. The oxygen molecules dissociated into  $\text{O}^{2-}$  anions at the high oxygen partial pressure side (feed side) and travel through lattice and released at low oxygen partial pressure side where these anions recombine again to form oxygen molecules. The oxygen flux is depended on the membrane electronic and ionic

conductivity. Flux is maximum when the electronic and ionic transference number is 0.5 for fixed total conductivity. The oxygen permeation rate is controlled by two main factors, one is the rate of interfacial oxygen exchange on both sides of the membrane and other is the rate of solid state diffusion within the membrane material. The oxygen transport through the membrane involved three progressive steps: the surface-exchange reaction on interface I, the simultaneous bulk-diffusion of charged species and electron/electron holes in the bulk phase and the surface-exchange reaction on the interface II [15]. After a certain thickness of the membrane the diffusion is the rate determining mechanism and when the thickness is reduced, oxygen transport across the interfaces I and II becomes the limiting factor and the variation of thickness and the mechanism affecting it is shown in Figure 16.

Figure 15 Different sections of ITM involved in oxygen transport during oxygen permeation

As long as the bulk diffusion mechanism is dominant, oxygen flux permeation can be increased by decreasing the thickness of the membrane. When the thickness reaches a characteristic membrane thickness  $L_c$ , the oxygen permeation is controlled by both surface exchange kinetics and bulk diffusion. For membrane thickness less than  $2L_c$ , the permeation flux becomes independent of membrane thickness and it can be seen figure 16. The characteristic thickness of the membrane is defined as the ratio of self-diffusivity of oxygen to surface exchange coefficient [39].

$$L_c = \left( \frac{D_s}{k_{io}} \right) \quad (1)$$

The transport of oxygen is influenced by many factors related to microstructure such as grain boundary diffusion and order-disorder phenomena, roughness and porosity of the membrane surface.

Figure 16 Variation of regime from bulk-diffusion to surface-exchange reaction limited with decreasing membrane thickness [38]

### 2.3.3 Bulk transport theory:

The diffusion process in the thick membrane is commonly the slowest step. The Wagner theory can be used to describe the oxygen flux  $J_{O_2}$  [40].

$$J_{O_2} = \frac{1}{16F^2L} \int_{\mu_{O_2}(II)}^{\mu_{O_2}(I)} t_i t_e \sigma_i d\mu_{O_2} \quad (2)$$

$$t_i = \frac{\sigma_i}{\sigma_e + \sigma_i} = \frac{\sigma_i}{\sigma_i} \quad (3)$$

where  $t_i$ ,  $t_e$  is the ionic and electronic transference numbers respectively which are defined as ratio of electronic ( $\sigma_e$ ) or ionic conductivity ( $\sigma_i$ ) over sum of them.

Equation (2) has been derived by assuming that local equilibrium exists between the two charged species such as oxygen ion and electron and a hypothetical neutral species such as molecular oxygen in the bulk oxide. For consideration, at least three species can contribute to the bulk-diffusion which are (a) oxygen vacancies, (b) electrons or (c) electron holes. Each of them might be the slowest moving species and therefore limiting the oxygen flux.

#### 2.3.3. (a) Oxygen vacancies diffusion:

In mixed ionic and electronic conducting membranes, the electronic conductivity dominates, that is  $\sigma_e \gg \sigma_i$ , the integral of equation (2) involves only  $\sigma_i$  as a function of oxygen partial pressure. Assuming ideal thermodynamic system, the chemical potential can be written as

$$d\mu_{O_2} = RT d \ln P_{O_2} \quad (4)$$

Nernst-Einstein correlation [41] for the ionic conductivity is expressed as,

$$\sigma_i = \frac{4F^2 V_o^{\bullet\bullet} D_v}{RT V_m} \quad (5)$$

$$D_v = D_v^0 \exp\left(-\frac{E_a}{RT}\right) \quad (6)$$

For average value of  $\sigma_i$  and for small oxygen partial pressure gradient the oxygen permeation flux equation can be integrated as,

$$J_{O_2} = \frac{RT}{16F^2 L} \bar{\sigma}_i \ln \frac{P_{O_2}'}{P_{O_2}''} \quad (7)$$

The above equation is valid for very rare cases such as the case of tubular membrane [42] working under 700°C-900 °C for partial pressure of oxygen at feed side is in between 0.09-1.0 atm.

In general, if the oxygen ionic conductivity can be correlated [43] to oxygen partial pressure in a simplified manner, then the oxygen flux can be given by,

$$\sigma_i = \sigma_i^o P_{O_2}^{-n} \quad (8)$$

$$J_{O_2} = \frac{RT}{4F^2 L} \sigma_i^o \left( P_{O_2}^{'-n} - P_{O_2}^{'-n} \right) \quad (9)$$

Kim et al [44, 45] have derived generalise form of equation describing oxygen permeation through tubular perovskite membrane assuming that density of vacancies at the interfaces does not change. Equation (10) shown below is for Bulk-diffusion limited region in tubular perovskite membranes.

$$J_{O_2} = \frac{\pi w C_i D_a}{2S \ln(r_1 / r_2)} \ln \left( \frac{P_{O_2}^{0.5}}{P_{O_2}^{0.5}} \right) \quad (10)$$

$$\text{where } D_a = \frac{\sigma_e D_i}{\sigma_e + \sigma_i} . \quad (11)$$

### 2.3.3. (b) Electron diffusion:

The electronic defects could be properly assumed and can be given in the equation (12). Furthermore, by using the law of mass action; equation (13) can be derived. The electronic concentration is proportional to  $P_{O_2}^{-1/4}$ , if the concentration of all other species (oxygen vacancies and interstitials) is much higher. Therefore, the electron concentration can be taken as constant, when  $t_i \approx 1$  (ionic conductivity is dominant). Therefore equation (2) can be modified resulting in equation (14). In this equation, electronic conductivity is a function of electron concentration as shown by equation (15). From the above mentioned assumptions the oxygen permeation flux is depended to  $-1/4^{\text{th}}$  order of oxygen partial pressure and is given by equation (16). The mentioned equations are best fitted with the results of Han et al [46], and Nigara el al [47].

$$n = \frac{K_{V_o^{\bullet\bullet}}^{1/2} [O_o^x]^{1/2}}{P_{O_2}^{1/4} [V_o^{\bullet\bullet}]^{1/2}} \quad (13)$$

$$J_{O_2} = \frac{RT}{16F^2L} \int_{P_{O_2}^*}^{P_{O_2}} \sigma_e d \ln P_{O_2} \quad (14)$$

$$\sigma_e \approx n \approx KP_{O_2}^{-1/4} \quad (15)$$

$$J_{O_2} = \frac{RT}{4F^2L} \sigma_e^o \left( P_{O_2}^{'-1/4} - P_{O_2}^{"-1/4} \right) \quad (16)$$

### 2.3.3. (c) Electron hole diffusion:

The electron holes equation can be represented as follows,

Further, by using law of mass action; equation (18) can be obtained. By the same assumptions used in electron diffusion, oxygen flux equation (19) can be derived which also shows the dependence of  $1/4^{\text{th}}$  order of partial pressure of oxygen and this has been reported by Han et al [46], Capoen et al [48] and Dou et al [49].

$$h = \frac{K_{O_o^x}^{1/2} P_{O_2}^{1/4} [V_o^{\bullet\bullet}]^{1/2}}{[O_o^x]^{1/2}} \quad (18)$$

$$J_{O_2} = \frac{RT}{4F^2L} \sigma_h^o \left( P_{O_2}^{1/4} - P_{O_2}^{*1/4} \right) \quad (19)$$

#### 2.3.4 Surface exchange- limited reaction:

This mechanism is dominant when the oxygen transport resistance in the bulk-diffusion phase becomes very small due to increase in the ionic or electronic conductivity or due to reduction in the thickness of the membrane. In this case, the Wagner equation is not applicable. Other relations were developed to explain the behaviour of oxygen transport within this regime. Dou et al [49] proposed a possible mechanism the surface reaction into bulk-diffusion as following:

(25) Surface exchange reactions are expected to be sequential and may consist of adsorption from the gas phase, charge transfer reaction between the adsorbed species and bulk including the reversed reactions as shown in Figure 17.

If the slowest moving species considered is  $O^x$  at the interface I, and using the law of mass action, the following relation for charged and absorbed oxygen species from

equation (20) and (21) applies. A proportional constant  $K$  represents the equilibrium constant.  $K$  is specific for each type of reaction as indicated in its subscript which refers to the primary product of the reaction.

$$K_{O_{(w)}} = \frac{O_{(w)}^2}{P_{O_2(g)}}$$

$$K_{O_{(w)}^x} = \frac{[O_{(w)}^x]P_{(w)}^2}{[O_{(w)}][V_{O(w)}^{\bullet\bullet}]}$$

Therefore,

$$[O_{(w)}^x] = \frac{K_{O_{(w)}}^{1/2} K_{O_{(w)}^x} P_{O_2}^{1/2} [V_{O(w)}^{\bullet\bullet}]}{P_{(w)}^2}$$

If the oxygen flux is proportional to the concentration of species  $O^x$ , then the oxygen flux can be represented as equation (26).

$$J_{O_2} = \alpha \left( P_{O_2}^{1/2} - P_{O_2}^{*1/2} \right) \quad (26)$$

where  $\alpha = \beta_1/L$  ;  $\beta_1$  is the bulk-diffusion step constant determined experimentally and  $L$  is the membrane thickness.

Kim et al [44] derived an equation which accounts for the surface exchange kinetics for tubular perovskite membranes which was used to fit the oxygen permeation data for  $\text{SrCo}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$  and  $\text{Sm}_{0.5}\text{Sr}_{0.5}\text{CoO}_{3-\delta}$ .

$$J_{O_2} = \frac{2\pi r_1 r_2 w C_i k_{io}}{S(r_1 + r_2)} \left( \sqrt{\frac{P'_{O_2}}{P^0_{O_2}}} - \sqrt{\frac{P''_{O_2}}{P^0_{O_2}}} \right) \quad (27)$$

Figure 17 Surface exchange and bulk diffusion mechanism

### 2.3.5 Generalized transport equation:

Incorporating all mechanisms into a single explicit equation was demonstrated by many researchers [49-56] with the following assumptions.

- i. The oxygen permeation rate across the membrane is governed by the flux of oxygen vacancies since the electronic conductivity in perovskite is much greater than its ionic conductivity.
- ii. A steady-state electric field gradient is negligible due to fast movement of electron holes (electronic holes is assumed to dominate the electronic conductivity).
- iii. Ideal gas behaviour is applied to the gas phase.

- iv. The radial diffusion is neglected while the diffusion coefficient of oxygen vacancies  $D_v$  is assumed to be constant.
- v. Surface-exchange reaction in the feed side is governed by equation (17) while the reverse of equation (17) applies to the permeate side, both with the rate constants  $k_f$  and  $k_r$  that are equal for both sides.
- vi. Concentration of electron holes is considered constant at both sides of the membrane while the law of mass action is applied for other components.

$$J_{O_2} = \frac{(k_r / k_f)(1/P_{O_2}'^{0.5} - 1/P_{O_2}''^{0.5})}{(1/k_f P_{O_2}'^{0.5}) + (2L/D_v) + (1/k_r P_{O_2}''^{0.5})} \quad (28)$$

The above equation (28) is derived for specific disk-shaped membranes and has been shown to fit the oxygen flux for LSCFO in the temperature range 750°C-950°C and for 0.21-1.0atm oxygen partial pressure at the feed side. In the equation, each term in the denominator represents resistance in the feed, bulk membrane and permeates side respectively.

Xu et al [52] carried out similar analysis for disc membrane LCSF6428 and a correlation is developed for steady state oxygen permeation flux.

$$J_{O_2} = \frac{D_v k_r [(P_{O_2}')^{0.5} - (P_{O_2}'')^{0.5}]}{2L(P_{O_2}'')^{0.5}(P_{O_2}')^{0.5} + ((P_{O_2}')^{0.5} + (P_{O_2}'')^{0.5})D_v} \quad (28)$$

Where  $D_v, k_f, k_r$  are functions of temperature and specific properties of the membrane and can be obtained by fitting experimental oxygen flux data as a function of temperature and oxygen partial pressure gradients.

The above equation can be rewritten in form as,  $J_{O_2} = \frac{\Delta P_{O_2}}{R_t}$

Where  $\Delta P_{O_2} = (k_r / k_f)(1 / P_{O_2}''^{0.5} - 1 / P_{O_2}'^{0.5})$  is oxygen pressure driving force across the membrane and  $R_t = R_{ex}' + R_{diff} + R_{ex}''$  is the total resistance to permeation, where

$$R_{ex}' = (1 / k_r (P_{O_2}')^{0.5})$$

$$R_{diff} = (2L / D_v)$$

$$R_{ex}'' = (1 / k_f (P_{O_2}'')^{0.5})$$

If any one step is limiting then its resistance dominates the total partial pressure difference, so the permeation flux based on the single step can be given as follows

$$\text{Bulk diffusion} \Rightarrow J_{diff} = \frac{\Delta P_{O_2}}{R_{diff}} = \frac{k_r D_v (1 / P_{O_2}''^{0.5} - 1 / P_{O_2}'^{0.5})}{2L k_f}$$

$$\text{Surface exchange: oxygen-rich side} \Rightarrow J_{ex}' = \frac{\Delta P_{O_2}}{R_{ex}'} = k_r (P_{O_2}'^{0.5} / P_{O_2}''^{0.5} - 1)$$

$$\text{Surface exchange: oxygen-lean side} \Rightarrow J_{ex}'' = \frac{\Delta P_{O_2}}{R_{ex}''} = k_f (1 - P_{O_2}''^{0.5} / P_{O_2}'^{0.5})$$

The value of  $D_v, k_f, k_r$  can be obtained by the following expressions.

$$D_v = D_v^0 \exp\left(\frac{-E_D}{RT}\right)$$

$$k_r = k_r^0 \exp\left(\frac{-E_f}{RT}\right)$$

$$k_r = K_r^0 \exp\left(\frac{-E_r}{RT}\right)$$

Where  $E_r, E_D, E_f$  is the activation energies (kJ/mol) and  $k_r^0, D_v^0, k_f^0$  are pre-exponential coefficients for reverse, bulk and forward reaction rate constants.

Tan and Li [50] derived the  $O_2$  permeation flux equation(30) for tubular membrane accounting for bulk diffusion of oxygen vacancies in the membrane and the surface oxygen exchange kinetics on either side of the membrane by considering no mass transfer resistance between gas and the membrane surface.

$$J_{O_2} = \frac{k_r \left[ (P_{O_2}')^{0.5} - (P_{O_2}'')^{0.5} \right]}{(R_m / R_{in}) (P_{O_2}'')^{0.5} + (2t_e (P_{O_2}'')^{0.5} (P_{O_2}')^{0.5} / D_v) + (R_m / R_o) (P_{O_2}')^{0.5}} \quad (30)$$

where,  $J_{O_2}$  is the oxygen permeation molar flow flux, mol/cm<sup>2</sup>-s,  $\Rightarrow R_m = \frac{R_o - R_{in}}{\ln(R_o / R_{in})}$ ,  $R_m$

is the average radius of the tubular membrane, in which  $R_o$  and  $R_{in}$  is the outer and the inner radii of the tubular membrane in cm,  $t_e$  is the effective thickness of the membrane wall and for symmetric membrane it is given as  $t_e = R_o - R_{in}$ .

It can be seen that the total permeation resistance is composed of three parts:

- i. The exchange reaction at the inner membrane surface (permeate side).

$$\Rightarrow R_1 = (P_{O_2}'')^{0.5} / k_r R_m / R_{in}$$

- ii. The bulk diffusion  $\Rightarrow R_2 = 2t_e k_f / k_r (P_{O_2}'')^{0.5} (P_{O_2}')^{0.5} / D_v$

- iii. The exchange reaction at the outer membrane surface (feed side).

$$\Rightarrow R_3 = (P_{O_2}')^{0.5} / k_r R_m / R_o$$

The  $P_{O_2}'$  and  $P_{O_2}''$  are the partial pressure of oxygen at the feed side and the permeate side respectively.  $R_1, R_2, R_3$  are the resistances to oxygen permeation as described above and these resistances has the units  $(\text{atm}^{0.5} \text{cm}^2 \text{sec/mol})$ .  $D_v$  is the diffusion coefficient of oxygen vacancies in the membrane ( $\text{cm}^2/\text{s}$ );  $k_f$  ( $\text{cm atm}^{-0.5} \text{s}^{-1}$ ) and  $k_r$  ( $\text{mol cm}^{-2} \text{s}^{-1}$ ) are the forward and the reverse reaction rate constants for the surface exchange reaction shown in equation (31):

The charged defects are defined using Kröger-Vink notation [15] where  $O_o^x$  represents lattice oxygen,  $V_o^{\bullet\bullet}$  the oxygen vacancy and  $h^{\bullet}$  the electron hole. Both, diffusion coefficient of the oxygen vacancy and the surface exchange reaction constants are function of temperature but independent of the oxygen partial pressures [57].

Tan et al [57] predicted these constants for LSCF6428 in analysis for oxyfuel combustion using membranes and are given in equations (32-34). In these equations,  $T$  is the local temperature in K.

$$D_v = 1.58 \times 10^{-2} \exp\left(\frac{-8852.5}{T}\right) \quad (32)$$

$$k_f = 5.90 \times 10^6 \exp\left(\frac{-27291}{T}\right) \quad (33)$$

$$k_r = 2.07 \times 10^4 \exp\left(\frac{-29023}{T}\right) \quad (34)$$

Wang et al [58] conducted oxygen permeation study in a tubular  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$  oxygen permeable membrane. Oxygen permeation flux was measured at different partial pressure on both side of the membrane for different membrane temperatures in the range of 700 and 900 °C. The experimental setup consist of a tubular membrane of dia 4.96 mm, shell of dia 29 mm and length 17.68 mm. Air ( $\text{O}_2$  and  $\text{N}_2$ ) is used as feed at shell side with mass flow rate of 300 ml/min and He is used as sweep gas in tube side with mass flow rate of 60 ml/min for varying oxygen partial pressure in shell side from 0.09 atm to 1 atm and for temperature range between 700-900 °C. The results show that the oxygen permeation flux increases with increase of partial pressure of oxygen at shell side for a constant temperature. The increase of temperature also greatly affects the permeation flux along with the partial pressure of  $\text{O}_2$  at the feed side. The analysis was

done considering two mechanism of transport of oxygen, one is surface exchange current model and other is bulk diffusion given by equations (26) and (10) respectively.

Guillodo et al [59] conducted experimental analysis for oxygen permeation through dense  $\text{Bi}_2\text{V}_{0.9}\text{Cu}_{0.1}\text{O}_{5.35}$  ceramic membranes. The oxygen permeation was decomposed in three steps: bulk diffusion, surface exchange between oxygen and oxygen vacancies at feed side and surface exchange between oxygen and oxygen vacancies at permeate side. The oxygen flux is modeled using Wagner theory [40] assuming that both surfaces of the membrane are in equilibrium with the imposed gas atmospheres. The oxygen permeation flux was correlated as equation (19). The experiments are done on three cells and out of which two cells are coated with porous gold layer. The amount of oxygen permeation flux was calculated by varying the pressure at the feed side between  $10^2$  and  $10^5$  Pa. The results show that permeation flux is proportional to the  $(P_1^n - P_2^n)$  where the best fit value of  $n$  obtained to be 0.5. The maximum value of oxygen flux was  $9.1 \times 10^{-7} \text{ mol cm}^{-1} \text{ min}^{-1}$  for 923 K and  $10^5$  Pa.

Taheri et al [60] made a comparison for the permeation of oxygen flux through three membranes SCF, LSCF (6482) and LSCF (8264). For a given membrane, the oxygen flux was found to be a function of temperature and partial pressures. The permeation of oxygen was assumed to be dominant by bulk diffusion as given by equation (7). The temperature was assumed 1153 K and the membrane thickness was 0.84 mm. The partial pressure of oxygen at the feed side was varied between 0.1-1.0 bar and the air mass flow rate was 150 mL/min and the sweep gas (He) flow rate was 25 ml/min. The flux

increased as LSCF (8264) <LSCF (6482) <SCF (82). The increase of flux was found to be proportional to the ratio of natural log of partial pressure of oxygen at feed to permeate sides and reaches a maximum value of  $1.0 \times 10^{-7}$  mol/cm<sup>2</sup>.s for LSCF(8462),  $1.7 \times 10^{-7}$  mol/cm<sup>2</sup>.s for LSCF(6482) and  $9.2 \times 10^{-7}$  mol/cm<sup>2</sup>.s for SCF(82).

Xuan et al [61] carried out numerical modeling by integrating the chemical kinetics for autothermal reforming (ATR) of biogas. The performance and characteristics of biogas for hydrogen production was investigated for a two-dimensional model based on the integration of chemical kinetics with the computational fluid dynamics. The analysis was done for three physical models; one was the conventional ATR reformer and other two with hydrogen membrane reformer and oxygen membrane reformer. The results obtained from the numerical investigation were compared with the experimental data of autothermal reforming of methane and the results were in good agreement.

An experimental investigation of oxygen permeation through perovskite membrane under vacuum and elevated pressures was carried out by Zhu et al [62]. The analysis was done by taking BSCFO material and the dimensions were OD 2.38 mm and ID of 1.4 mm and length of 400 mm. The feed mass flow rate was varied from 100-200 ml/min and the pressure at the feed side ranged from 1 atm to 7 atm and the permeate side is kept at vacuum pressure of 100 Pa. The experiments are done at elevated temperatures of 825-925°C. The maximum permeation reported was 9.5 cm<sup>3</sup>/cm<sup>2</sup>-min at 925°C and 7 atm pressure at feed site for 200 ml/min mass flow rate of air at feed.

Tan et al [57] studied oxy-fuel combustion using a catalytic ceramic membrane reactor. In this experimental work, Tan et al used perovskite  $\text{La}_{0.6}\text{Sr}_{0.4}\text{Co}_{0.2}\text{Fe}_{0.8}\text{O}_{3-\alpha}$  (LSCF6428) hollow fiber oxygen-permeable membranes, prepared by phase inversion/sintering technique, for combustion in a hollow fiber membrane reactor (HFMR). It was assumed that the furnace gives a symmetrical temperature profile. A second HFMR was prepared using platinum coated LSCF6428 hollow fiber membranes. The methane was fed into inner side, through the catalyst bed while the air supply was introduced concurrently into the shell side (outer diameter) of the hollow fibers. The total time was ten minutes. All experiments were performed at 1 atm on both the shell and inner sides. In modeling of the membrane reactor assumptions in the model equations are made such as, radial concentration gradients and the temperature changes due to reaction can be neglected. The modeling equations are a group of ordinary differential equations and are solved numerically using MATLAB. The results showed that as the methane feed flow rate increases, more oxygen is converted and the oxygen conversion eventually approaches 100%. Furthermore no products other than carbon dioxide were observed during the experiments. It was concluded that the granular LSCF6428 catalyst shows a high catalytic activity to methane combustion. At high methane feed flow rate, the experimental data were in better agreement with the simulated results using the faster reaction kinetics. The oxygen concentration in the product stream was found to increase as the temperature was increased indicating that the oxygen permeation rate is higher than the oxygen consumption rate due to the reactions. The conversion for both methane and oxygen was found to increase as the reaction rate increases. Both effect of increasing

the temperature or decreasing the methane feed flow rate tend to increase methane conversion. It was shown that the model can adequately predict the trend of the experimental results both for the methane conversion and the oxygen permeation rate. It was found that methane combustion in the HFMR is dependent on the rate of oxygen permeation through the membranes. The results showed that the oxygen permeation rate is increased due to platinum coating and, as a result, the methane conversion is increased. The coating decreased the outer surface exchange resistance to oxygen permeation leading to the improvement of oxygen permeation rate and hence methane conversion.

The performance of ITM reactors were studied in different configurations such as gas single-tube, hollow-fiber membrane module, capillaries and monolithic multi-channels. Of all the configurations, the hollow-fiber module has highest surface area and is suggested for use in oxyfuel combustion applications [63]. Table 1 shows some of the researchers who carried out experiments on tubular membrane for oxygen permeation.

## 2.4 Numerical work in the area of membranes

Numerical simulations of membrane using finite-volume approach are very few. Mirella et al [76] carried out numerical and experimental investigation of mass transfer performance of Pd-Ag Membrane Modules for Hydrogen separation. In the analysis, impact of concentration polarisation and non-ideal flow on design of membrane separation units was evaluated by using Computational Fluid Dynamic. In the analysis, the source and sink terms are introduced on either side of the membrane boundary cell in order to account for the permeation of hydrogen in the numerical study developed by Coroneo et al [77]. The study covered different module configuration for H<sub>2</sub> and N<sub>2</sub>

mixture and compared with the experimental results which were found to be in good agreement. The analysis extended to the use of baffles which permits the production of compartments inside the module, avoiding mixing and increase permeation driving force. The results show the separation performances of the module increases with the number of baffles. In all modules, studied the module with baffle resulted in maximum permeates of  $H_2$ .

Shigeo Goto [78] studied the effect of hydrogen permeation rate through composite palladium membrane for tubular configuration. A palladium film was coated on composite membrane tube. The analysis was done for increasing temperatures for two different modes. In the first mode, CP mode,  $H_2$  was passed through the tube and pressure was reduced in shell side. Therefore,  $H_2$  permeates first ceramic tube and then through the palladium film. In the second mode, PC mode,  $H_2$  was passed from shell side and pressure inside the membrane tube was reduced and  $H_2$  permeates first through palladium film then composite tube. The numerical models were based on the combined resistances of both palladium film and composite support. From the results it showed that with increase of temperature, permeation rate increases under CP mode.

A CFD modelling of inorganic membrane modules for gas mixture separation was carried out by M Coroneo et al [77]. First, they derived the permeation coefficient, based on the transport mechanisms for the gas molecules across the membrane. The basics of molecular diffusion, Knudsen diffusion and viscous (Poiseuille) flow, and used in the source term formulation in the continuity and species transport equations. Of all the

mechanisms, the molecular diffusion was dominant on  $H_2$  permeation at high pressures. The mole fraction and permeation rate of hydrogen increases with increase of working pressure and a good agreement with the experimental results was found.

Staudacher et al [79] conducted simulative analysis of mass transfer effects in gas and vapour permeation modules. The study relates the effect of concentration polarisation and flow distribution with spacers between two membrane surfaces. Calculations of permeation as a function of temperature, pressure and composition were done using finite-volume method. The use of baffles in the model which separates membrane into a number of compartments helped in velocity control of feed. The flow through the membrane was implemented as a sink in the basic transport equation for each finite cell. A user-defined function (UDF) was implemented for the transport from the membrane using a function for flux proportional to partial pressures. Similar to the work Staudacher et al [79], it was found from the results that the driving force obtained was due to concentration polarisation and the use of spacers which affects the performance of membrane.

The above literature shows a great potential of ITMs in optimizing the power generation systems and giving a breakthrough towards clean energy production. Using these ITMs many probable power cycles [29-35] were proposed and some of them [29-32] were implemented without integration as combustor. Currently, research has been focusing towards the ways of integrating the ITMs with combustion chamber [33-36]. The study of

fluid dynamics and membrane behaviour with the combustion has not been studied yet in designing the combustion chamber integrated with ITMs.

Many researchers [37-61] have examined the performance of these membranes experimentally for oxygen separation. The experiments were done in both disk type and tubular membranes to study the permeation performance based on the geometrical and membrane characteristics. For Oxygen transport reactor, the feasible design at the initial stage is the concentric tubes with air in the outer side and sweep gas (inert) in the core side in order to sweep out the permeated oxygen. The effect of flow rates of sweep gas and air has been studied [58] and it shows increase of permeation with increase of sweep gas flow rates. It is tedious to do experiments each time to study the characteristics of such membrane. One of the alternatives is to use computational fluid dynamics to study the behaviour of these membranes.

If the permeate side is reacting, then the permeation performance will change due to reduced oxygen partial pressure. So, it is important to know the performance of these membranes when there is a reacting zone in order to integrate with power plant. Modeling the phenomenon of species transport from one side to the other numerically was studied [76-78] for Hydrogen separation through Pd-Ag membranes without reacting zone at permeates side. Zhang [73] and Smith [74] modeled the behaviour of ITMs for one dimensional model assuming that change of oxygen mole fraction on the surface of membrane and in the bulk is negligible. This assumption is not fully valid for natural gas

combustion application since the mole fraction of oxygen will reduce from membrane surface to bulk as it will be consumed by the methane.

From the above discussion, it is evident that all of the numerical studies done are one dimensional and mostly for separation only. If we have the combustion at permeate side then it is important to know the combustion and permeation characteristics. So in order to study the behaviour of species in the whole domain the problem must be solved assuming axisymmetric velocity and thermal fluids.

# CHAPTER 3

## MODEL DEVELOPMENT

This chapter consists of three sections. The first section gives detailed information about formulating the permeation of oxygen through the Ion Transport Membrane. The second section explains the combustion chemistry and reaction mechanism. The last section of this chapter defines the numerical scheme and boundary conditions.

### 3.1 Membrane Permeation model

Dense perovskite membranes of type  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$  is selected since the oxygen flux obtained is highest with it as reported in table 1 and it is good conductors of both types with electron carriers and oxygen ion and high permeation are reported through these membranes [58]. Mechanism of oxygen transport through these membranes is classified into two types: exchange reactions on the membrane surfaces and the ionic diffusion through bulk diffusion [80] and it is discussed earlier in chapter 2. These two mechanisms are interrelated by a characteristic thickness of membrane  $L_c$  which is related to the ratio of self-diffusivity of oxygen to surface exchange coefficient ( $D_s/k_{io}$ ) [45]. If the thickness of the membrane is greater than the characteristic thickness, then bulk transport dominate, if the thickness of the membrane is less than characteristic

thickness then oxygen transport is equally limited by both surface exchange kinetics and the bulk diffusion.

Figure 18 Mechanism of Oxygen transport through dense Ion transport membrane by considering Surface exchange mechanism

The mechanism of oxygen transport through the dense perovskite  $Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$  membrane is shown in Fig. 18. At feed side oxygen molecules are absorbed on the membrane surface and converted in oxygen ions. These oxygen ions then migrate to permeate side through the bulk via the oxygen vacancies and then it gets recombine with the holes to form oxygen molecules. The oxygen permeation through these dense, mixed conduction membranes has been by the equation (35) for the case of steady-state, diffusion limited oxygen transport.

$$J_{O_2} = \frac{2\pi r_1 r_2 w C_i k_{io}}{S(r_1 + r_2)} \left( \sqrt{\frac{P_1}{P_0}} - \sqrt{\frac{P_2}{P_0}} \right) \quad (35)$$

Where  $r_1$  and  $r_2$  are the outer and the inner radius of the membrane tube respectively,  $w$  is the effective length of the tube,  $S$  is the effective area of the membrane tube,  $C_i$  is the density of oxygen ions,  $k_{io}$  is the surface exchange coefficient,  $P_1$  is the partial pressure of oxygen at the feed side,  $P_2$  is the partial pressure of oxygen at the permeate side and  $P_0$  is 1 atm oxygen pressure. From above equation is valid if only the surface exchange limited to oxygen transport and the oxygen permeation flux  $J_{O_2}$  should be linearly proportional to the pressure term  $(P_1/P_0)^{0.5} - (P_2/P_0)^{0.5}$ .

The permeation of oxygen flux has been investigated experimentally under different pressure at feed side and temperatures for different material configurations. Many relations has been derived for oxygen permeation for such conditions as ionic diffusion as well as the surface exchange reactions on the membrane surface through the bulk material as mentioned in chapter 2.

### 3.1.1 Methodology:

For the computational modeling of the performance of the OTR membrane, the commercial code FLUENT 12.1.2 is used. The study focused on the effect of oxygen partial pressure across the membrane and the membrane temperature on the oxygen permeation flux. A CFD model has been developed to predict the performance of ITM

membrane of the type  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$  for oxygen separation. In general, separation of gas from a mixture through membrane can be modelled by considering two different phenomena, the fluid dynamic behaviour of the gas mixture in the membrane module and the transport of the species in the mixture across the membrane.

### 3.1.2 Governing Equations:

The numerical simulations are based on the CFD methodology developed by Coroneo et al. [76] which was developed in the realm of a finite-volume method. The velocity and the pressure fields of the gas mixture are obtained from the numerical solution of the mass, momentum and energy equations, while the species concentration distribution and the fluxes at the permeate and the feed side are obtained by the scalar convection-diffusion equation including source/sink term to account for the mass flow of the species across the membrane. The following equations for conservation of mass, momentum, energy and species for Newtonian fluids are considered:

$$\nabla \cdot (\rho \mathbf{U}) = S_i$$

$$\nabla \cdot (\rho \mathbf{U} \mathbf{U}) = -\nabla p + \mu \nabla^2 \mathbf{U}$$

$$(\rho C_p) \mathbf{U} \cdot \nabla T = \nabla \cdot (k \nabla T)$$

$$\nabla \cdot (\rho \mathbf{U} Y_i) - \nabla \cdot (\rho D_{i,m} \nabla Y_i) = S_i$$

Where  $\mathbf{U}$  is the velocity vector,  $\rho$  is the fluid density,  $p$  is the pressure,  $\mu$  is the dynamic viscosity,  $S_i$  is the source or sink term. The  $S_i$  source/sink term is account for the mass

flow of species across the membrane. At the membrane boundary cells the species ( $O_2$ ) are allowed to disappear from one of the membrane sides (air side) through a sink term and to come out on the other (sweep side) through a source term. To apply this methodology the preliminary knowledge of the permeability characteristic of the membrane is required to formulate the source term. In the present work, the Oxygen transport membranes have been considered, which are permeable to oxygen only; therefore the source term takes into consideration only oxygen permeation.

$$S_i = \begin{cases} + \frac{J_{O_2} \cdot A_{\text{cell}} \cdot MW_{O_2}}{V_{\text{cell}}} & \text{at low partial pressure of } O_2 \\ - \frac{J_{O_2} \cdot A_{\text{cell}} \cdot MW_{O_2}}{V_{\text{cell}}} & \text{at high partial pressure of } O_2 \end{cases}$$

The term  $S_i$  is equivalent to zero unless  $i=O_2$  and the computational cell is adjacent to the membrane. The diffusion coefficient was determined by specifying, the binary mass diffusion coefficient of the component  $i$  in the component  $j$  (other species). The corresponding diffusion coefficient in the mixture is computed as follows [81]:

$$D_{i,m} = \frac{1-X_i}{\sum_{j,j \neq i} \left( \frac{X_j}{D_{i,j}} \right)}$$

The binary mass diffusion coefficient,  $D_{i,j}$ , is calculated by Chapman-Enskog formula using the kinetic theory [82]. Special source terms are applied in the continuity and species transport equations in the computational cells adjacent to the membrane. It is worth observing that the driving force in the source term is evaluated adopting local

values. Fluid density is calculated using ideal gas law. Density, viscosity, specific heat and thermal conductivity in the mixture according to the ideal gas mixing laws as follows [82] and same method of calculating these properties was also used by Nick and Alexander [83, 84] for modeling ITM model.

$$\rho_{\text{mix}} = (P_{\text{op}} + P) / \mathfrak{RT} \sum_i (m_i / M_i)$$

$$C_{p, \text{mix}} = \sum_i m_i C_{p, i}$$

$$\lambda_{\text{mix}} = \sum_i \left[ X_i \lambda_i / \left( \sum_j X_j \varphi_{i,j} \right) \right]$$

$$\mu_{\text{mix}} = \sum_i \left[ X_i \mu_i / \left( \sum_j X_j \varphi_{i,j} \right) \right]$$

$$\varphi_{i,j} = \frac{\left[ 1 + (\mu_i / \mu_j)^{1/2} (M_j / M_i)^{1/4} \right]^2}{\left[ 8(1 + (M_i / M_j)) \right]^{1/2}}$$

### 3.1.3 User Defined Function (UDF):

The equation developed by Kim et al [44] shown by equation (35) used by Haihui et al [58] to investigate the equation validity and found promising good. The O<sub>2</sub> permeation equations (35) involve the global partial pressures of O<sub>2</sub> of feed and permeate side. So, in order to convert global partial pressure terms to local partial pressure fitting of

experimental data is done and develop an equation which accounts for local O<sub>2</sub> partial pressures.

$$J_{O_2} = K_1 K_2 (T) \left( \sqrt{\frac{P_1}{P_0}} - \sqrt{\frac{P_2}{P_0}} \right)^{0.623} \quad (36)$$

$$K_1 = \frac{2\pi r_1 r_2 w}{S(r_1 + r_2)}$$

Where  $K_1$  is a geometric constant and  $K_2$  is a constant which depends on temperature.

Permeation of oxygen across the membrane is modelled using a series of user-defined functions that are written in VC++ and compiled and hooked in FLUENT 12.1.2 software. The issue of hydraulic jump across the membrane was resolved by patching the cells from the upper and lower zones with two different values of initial partial pressures of species. The source and sink terms in the UDF will be calculated by using the relation given below [58].

$$S_i = \frac{A_{\text{cell}}}{V_{\text{cell}}} \frac{2\pi r_1 r_2 w C_i k_{io}}{S(r_1 + r_2)} \left( \sqrt{\frac{P_1}{P_0}} - \sqrt{\frac{P_2}{P_0}} \right)$$

$$S_i = \frac{A_{\text{cell}}}{V_{\text{cell}}} \frac{2\pi r_1 r_2 w C_i k_{io}}{S(r_1 + r_2)} \left( \left( \frac{X_1 P}{P_0} \right)^{0.5} - \left( \frac{X_2 P}{P_0} \right)^{0.5} \right)$$

$$S_i = \frac{A_{\text{cell}}}{V_{\text{cell}}} K_1 K_2 \left( \left( \frac{X_1 P}{P_0} \right)^{0.5} - \left( \frac{X_2 P}{P_0} \right)^{0.5} \right)^{0.623}$$

The three different Macros used in UDF are ‘Define Initialize’, ‘Define Source’ and ‘Define Adjust’ as defined in FLUENT software. These macros link the cell index across the membrane which allows the addition and subtraction of the source term in continuity and species transport equation. Additionally, the UDF updates the solver data with the new parameter at the membrane wall for every iteration. The partial pressure given in the oxygen flux equation is calculated as concentration  $Y_i$  (% wt.) and the following flowchart (Figure 19) is applied for solving the  $O_2$  permeation flux. The mass fraction,  $Y_i$ , will be converted into mole fraction and then applied in calculating the source term.

Figure 19 Solution strategy for oxygen transport through the membrane.

### 3.2 Combustion Mechanism

The kinetic mechanisms used to model hydrocarbon combustion are generally composed of a large number of elementary reactions to describe a single comprehensive overall reaction in which the initial fuel and oxidizer combine to form the final products. The rates in which reactions proceed are primarily dictated by collisions of two molecules that may have the capability to react. Therefore, the most common elementary reactions used in mechanism construction are bimolecular in which two species collide and react to form two new species. To illustrate, consider an arbitrary bimolecular second order reaction

The rate at which such reaction proceeds is proportional to the concentration of the reactant species,

$$\frac{d[A]}{dt} = -k[A][B]$$

where the notation  $[A],[B]$  denotes the molar concentration of species A and B. The rate constant  $k$  is a function of temperature  $T$  and is the parameter used to describe each elementary reaction composing the entire kinetic mechanism [85,86,87]. A reaction will only take place, however, if the colliding molecules possess an adequate amount of energy called the activation energy  $E_a$ . the kinetic theory shows that the fraction of all collisions that possess energy greater than  $E_a$  is given by the Boltzmann factor  $\exp(-E_a/RT)$

Determination of reaction rates also requires that the frequency of molecular collisions be taken into account in the form of a pre-exponential factor A. The rate constant k is then typically expressed in a modified Arrhenius form as

$$k = AT^{\beta} \exp\left(\frac{-E_a}{RT}\right)$$

Where A,  $\beta$  are parameters determined experimentally and R is the universal gas constant. The exponent  $\beta$  becomes particularly important in systems where temperatures vary widely.

The most common combustion processes encountered in engineering field are those which convert a hydrocarbon fuel into carbon dioxide and water. These combustion reactions are usually exothermic in nature.

### 3.2.1 Reaction Mechanism for methane combustion:

The Single step kinetic reaction mechanism for combustion of methane also follows the same mechanism as shown below.

$$k = AT^{\beta} \exp\left(\frac{-E_a}{RT}\right)$$

$$\frac{d[\text{CH}_4]}{dt} = -k[\text{CH}_4]^{n_{\text{CH}_4}} [\text{O}_2]^{n_{\text{O}_2}}$$

$$\frac{d[O_2]}{dt} = -2k[CH_4]^{n_{CH_4}} [O_2]^{n_{O_2}}$$

$$\frac{d[CO_2]}{dt} = k[CH_4]^{n_{CH_4}} [O_2]^{n_{O_2}}$$

$$\frac{d[H_2O]}{dt} = 2k[CH_4]^{n_{CH_4}} [O_2]^{n_{O_2}}$$

$$n_{CH_4}=0.2, n_{O_2}=1.3, n_{CO_2}=0, n_{H_2O}=0$$

$$A=2.119 \times 10^{11}, E_a = 2.027 \times 10^8 \text{ J/kg-mol}, \beta=0$$

Now using both membrane permeation model and combustion together will be a challenging part in order to model ITM reactor.

The oxygen transport reactor considered for study is of cylindrical shape in which a mixture of  $CH_4$  and  $CO_2$  are injected from one side and the oxygen permeates through the ITM walls of the reactor. The study focuses on the effect of the sweep gas mixture ( $CO_2$  and  $CH_4$ ) on the oxygen permeation process through the ITM membrane for the two cases of co-current and counter-current flow regimes and validation of the computational model against the available experimental data. The ITM membrane has a tubular shape similar to that used in the experimental work by Wang et al. [58] and a schematic of the membrane is shown in Figure 20. The membrane comprised of a highly dense perovskite BSCFO with an effective surface area  $12.56 \text{ cm}^2$  while the area used for model validation is of  $2.531 \text{ cm}^2$ . The experimental conditions were maintained at steady state with

laminar flow on both sides. The outcome of this study represents the first step in designing ion transport reactors since it provides information about the size and geometry of the combustion region (based on the oxygen content of the mixture) for different mass fraction of  $\text{CH}_4$  and  $\text{CO}_2$  of the sweep gas.

After studying the cold combustion (mixing) the reaction mechanism is activated to study the temperature and combustion characteristics of the ITM reactor. The axisymmetric model of ITM reactor is shown in figure 21.

### 3.3 Numerical Scheme and Boundary conditions

In these simulations, the properties of the gas mixture at inlet of both inner and outer regions were first assumed the same as those considered in the experimental work of Wang et al. [58]. The discretization of the governing equations is done using a segregated solver in which each governing equation is solved separately. The Semi-Implicit Method for Pressure-Linked Equations (SIMPLE) formulation was used as a part of pressure-velocity coupling algorithm [88]. The convergence criteria for the continuity and momentum parameters were set to  $10^{-6}$  and species and energy equation were set to  $10^{-9}$  to allow sufficient iterations for complete convergence at all grid points. The gas density is calculated using the ideal gas law and the gas viscosity, specific heat and thermal conductivity are calculated as a mass fraction-weighted average of all species. The specific heat of each species is calculated using a piecewise polynomial fit of temperature [81] and tabulated in table 2. To obtain a stable solution, under-relaxation factors of 0.3 and 0.7 were used for pressures and velocities at all nodal points in the solution domain. The pressure staggered scheme (PRESTO) was used for pressure and the second-order upwind discretization scheme was used for momentum, species and energy equation [88]. To enhance the convergence of the numerical solution, the Aggressive Advanced Multigrid (AMG) scheme was used. The AMG cycle type for the coupled equations involving pressure, momentum, energy and species were set to fixed ‘F-cycle’ as a recursive process [81]. To avoid irregular convergence patterns ‘Biconjugate Gradient Stabilized Method’ (BCGSTAB) was employed. Properties of species used in single step combustion reaction are tabulated in table 3.

# CHAPTER 4

## NUMERICAL STUDY

The control volume approach is used to discretize the governing equations using FLUENT<sup>TM</sup> 12.1.2 code [81]. All variables are computed at each grid point except the velocities, which are determined midway between the grid points. A staggered grid arrangement is used in the present study, which links the pressure through the continuity equation and is known as SIMPLE algorithm [88].

The permeation of oxygen through the membranes and combustion is solved as a two dimensional axisymmetric problem using the double-precision solver. In addition to the scaled residuals, the temperature, mass fraction of CO<sub>2</sub> and H<sub>2</sub>O (in case of combustion) at the outlet of the fuel zone is monitored using surface monitors to ensure convergence. Second order upwind schemes are used for discretization of momentum and energy equations.

### 4.1 Grid Independence

A numerical mesh generator GAMBIT is used to create the geometry and mesh the domain using hexahedral elements. A fine mesh is created to capture the large gradients normal to the flow direction. Three different grids for ITM reactor model of figure 21 with 10000, 12500 and 15000 are created to examine the grid independence. Figure 22

compares the mass fraction of  $O_2$  along the axis obtained using the three grids by considering  $CH_4$  at the fuel inlet without combustion and shows a good agreement between the mass fraction values. Figure 23 shows the mass fraction of oxygen through the membrane for the above mentioned grids with combustion and it can be seen that for all the three grids the  $O_2$  mass fractions are in good agreement. Figure 24 shows the temperature variation for the same three different grids and found in very good agreement. From the above analysis, it can be concluded that the solution is grid independent for the selected grids.

## 4.2 Validation

In order to verify the accuracy of the computational model, the performance of the ion transport reactor with the dimensions given in Figure 20 was predicted and compared with the experimental data of Wang et al. [58]. In this problem, the oxygen permeation flux through the membrane (BSCFO type) is investigated for different partial pressures and temperature. The air in the feed side is considered as a mixture of only  $O_2$  and  $N_2$  and the  $O_2$  partial pressure is changed by changing the mole fraction. The air flow rate is 300 ml/min and Helium was used as sweeping gas in the inner region with a flow rate of 60 ml/min. The simulations are carried out for three temperatures and for oxygen partial pressures ranging from 0.09 atm to 1.0 atm. In all simulations, the pressure within the reactor is assumed atmospheric. Figure 25 shows the variation of  $O_2$  permeation flux and  $O_2$  partial pressure at the reactor outlet for different values of  $O_2$  partial pressure at inlet of the outer region considering operation at three different temperatures. The figure shows a significant increase in the  $O_2$  permeation flux with the increase of oxygen partial pressure in the feed side. The figure also shows a considerable increase in the oxygen flux at higher temperatures. A simple comparison between the model prediction and the measured values of  $O_2$  permeation flux shows a good accuracy especially at high oxygen partial pressure in the feed side. The largest deviation was about 15% occurring at 900°C and 0.19 atm. This deviation may be attributed to experimental uncertainties at high temperatures. The outlet partial pressure of  $O_2$  at permeate side is also predicted and compared with the experimental results and shown above in Figure 26. The comparison with experimental measurements shows a good agreement over all the partial pressure

range ( $P_1$ ) with maximum deviation of the same order ( $\approx 15\%$ ) occurring at the high temperature of  $900^\circ\text{C}$  and  $P_1=0.19$  atm.

Figure 25 Variation of O<sub>2</sub> permeation flux with oxygen partial pressure at inlet of shell side, (■□▼), experimental data; ( — ), present numerical results

Figure 27 shows the variation of the O<sub>2</sub> permeation flux over the reactor length at different operating temperatures and different inlet partial pressures ( $P_1$ ). It is clear from the figure that the O<sub>2</sub> permeation rate is high in the vicinity of the reactor entrance and decreases downstream. This is attributed to the reduction in O<sub>2</sub> partial pressure difference across the membrane towards the exit section. As the temperature of membrane increases, the activation energy of the surface exchange increases resulting in higher permeation rates.

Figure 26 Variation of  $O_2$  permeation flux and  $O_2$  outlet partial pressure with  $O_2$  partial pressure in the outer region. (■□▼), experimental data; ( — ), present numerical results

Similarly, the permeation rate increases with the  $O_2$  partial pressure on the feed side. Figure 28 shows the variation in  $O_2$  concentration at the permeate side under different conditions of partial pressure values ( $P_1$ ). The figure indicates that the permeation rate increases as  $P_1$  increases. The figure also shows a maximum concentration of 0.21 in the case of  $P_1 = 0.09$  atm, this increases to around 0.94 as the pressure  $P_1$  reaches 1.0 atm.

The  $O_2$  mass fraction shown in figure 28 is related with mole fraction which is nothing but partial pressure since the reactor is working under atmospheric conditions. From this, it can be clearly seen that with increase of partial pressure at feed side then partial pressure difference across the membrane is increased leading higher  $O_2$  permeation flux. Thus, it is advantageous to work at high  $O_2$  partial pressure at feed side but the objective

of this work is to separate  $O_2$  from air. In that the  $O_2$  concentration is fixed to 21% by volume. Hence for the separation of  $O_2$  with these membranes having sweep gas mixture ( $CH_4$  and  $CO_2$ ) partial pressure of  $O_2$  is fixed to 0.21 atm. The effect of difference of partial pressure across the membrane can be seen in figure 29. It is evident that higher the difference of partial pressure more the  $O_2$  permeated and it is experimentally validated as shown. So in order to increase the difference in partial pressure one method is to create vacuum at permeate side and other method is to reduce the incoming  $O_2$  by reforming or combustion.

The above comparisons give enough confidence in the computational model for investigating the effect of using the fuel mixture ( $CH_4$  and  $CO_2$ ) as sweeping gas on the performance of the ITM reactor.

(● ▲ ■) shows the experimental data and ( — ) shows the numerical results.

In order to validate combustion model, the Norton and Vlachos micro burner geometry [89] is selected as shown in figure 30. The micro-burner consists of two parallel, infinitely wide plates of length of 1 cm. The distance between the two plates is 0.6 mm and the thickness of the wall is taken as 0.2 mm. The case is modeled as 2-D symmetric about the centre line as the gravity effects are neglected. The wall top is given a boundary condition of no convective heat transfer. The sides of the wall are insulated with no heat flux boundary condition. At the inlet, mass flow inlet boundary condition is applied and

at the outlet a known pressure is specified. At the interface between the wall and the fluid, no-slip boundary condition and no-species flux normal to the wall surface are employed. The parameters used are  $V_0 = 0.5$  m/s, thermal conductivity of wall =  $7.5$  W/m/K,  $h = 0$  W/m<sup>2</sup>/K. Premixed, stoichiometric methane/air mixtures are fed to a micro-burner. A finite-difference method is used to discretize the 2-D continuity, momentum, energy and species conservation equations in the fluid and the 2-D energy equation in the wall. Steady-state simulations are performed. Figure 31 shows the centre line temperature profile for premixed air/methane combustion for micro-burner. It is evident that the temperature profile obtained by Norton and Vlachos [89] is in good agreement with the present calculation. With this combustion results validation we get enough confidence to perform the combustion in ITM reactor with O<sub>2</sub> separation.

# CHAPTER 5

## RESULTS AND DISCUSSION

This chapter consists of two sections. In the first section, the oxygen transport reactor is simulated on cold basis and the effect of O<sub>2</sub> permeation flux on sweep gas mixture variation is studied and in the second section, the combustion characteristics of methane within the reactor is presented and the effect of reducing environment on O<sub>2</sub> permeation flux is discussed. The results presented in each section pertain to the objectives discussed in the first chapter.

### 5.1 Cold Combustion (Mixing)

In this work, the performance of an ion transport reactor utilizing ITM-BSCFO membrane [Ba<sub>0.5</sub>Sr<sub>0.5</sub>Co<sub>0.8</sub>Fe<sub>0.2</sub>O<sub>3- $\delta$</sub> ] with the dimensions given in Figure 21 was investigated. The reactor operates with air at the feed side and a mixture of CH<sub>4</sub> and CO<sub>2</sub> (as sweep gas) at the permeate side. The study focuses on the effect of pressures and temperatures at the feed side on the composition of the gas mixture at the permeate side when operating at 1 atm. Air is assumed to contain only N<sub>2</sub> (77% by mass) and O<sub>2</sub> (23%) in all cases.

Figures 32 and 33 present the contours of ratio of mass fraction of oxygen to methane ratio within the domain of the reactor for the co-current and counter-current regimes, respectively. This ratio is important to characterize the region in which combustion can take place. In both regimes, the ratio of oxygen to methane increases for decreasing percentage of  $\text{CH}_4$  at inlet of the sweep side. As a result, the combustible region increases with the decrease of the  $\text{CO}_2$  to  $\text{CH}_4$  ratio. The influence of the sweep ratio (percentage of  $\text{CO}_2/\text{CH}_4$  by mass) on the oxygen methane mixture composition for the co-current regime is shown in Figure 32. In order to control the oxygen to methane ratio within the reactor and to determine the regions of combustible mixture, the sweep ratio varies from 0% to 98%. The inlet region shows a rich mixture having a fuel to oxygen ratio outside the flammability region. This is attributed to the low oxygen flux at inlet of the reactor. The size of this region diminishes as the sweep ratio increases. The mixture starts to fall within the flammability limits at approximately  $x/L = 0.05$ . The stoichiometric mixture (ratio of  $\text{O}_2/\text{CH}_4$  by mass equal to 4.0) appears only for  $\text{CO}_2/\text{CH}_4$  ratio of 0.98/0.02. For this ratio, a large region around the stoichiometric value that lies within the flammability limits (regions having the ratio of  $\text{O}_2/\text{CH}_4$  between 1.4 and 8.4) appeared.

The influence of the sweep ratio on the oxygen methane mixture composition for the counter-current regime is presented in Figure 33 where the percentage of  $\text{CO}_2$  changes from 0% to 98%. Regions having  $\text{O}_2/\text{CH}_4$  mixture within the flammability limits are shown at high sweep ratios in Figure 33. The figure indicates that changing the sweep ratio influences the boundaries of the flammability limits significantly. For example, for

zero sweep ratio the region of flammability limits is formed only in the entrance region  $[0 < X/L < 0.05]$ . As the sweep ratio increases, the size of this region increases and the region out of flammability limits diminishes. As well, at low sweep ratios, the mixture is shown to be lean and does not reach stoichiometric composition. As the sweep ratio reaches 0.94/.06, the mixture is found to include a combustible region around the stoichiometric ratio. As the sweep ratio reaches 0.98/.02, the mixture becomes mostly lean mixture. A comparison between Figures 32 and 33 shows that the counter flow regime exhibits better mixing of fuel and oxygen. In addition, the counter flow regime results in more homogeneous difference in  $O_2$  partial pressures across the membrane and, therefore, provides more uniform oxygen flux along the reactor wall. Figures 34 and 35 present the distribution of mass fractions of  $O_2$ ,  $CH_4$  and  $CO_2$  along the reactor axis for different sweep ratios for the co-current and counter-current flow regimes, respectively. The figures indicate that the mixture is rich at low sweep ratios and reaches stoichiometric at higher values.

The variation of  $O_2/CH_4$  ratio in the mixture along the reactor length is presented in Figures 36 for the two cases of co-current and counter-current flow regimes. The results indicate that the sweep ratio has a significant effect on the magnitude and distribution of the  $O_2/CH_4$  mixture along the reactor. In the counter flow regime, the maximum ratio of  $O_2/CH_4$  attained along the reactor is higher than that in the co-current case for all sweep ratios. On the other hand, a uniform distribution of the  $O_2/CH_4$  ratio occurs over a larger distance along the reactor in the co-current regime for almost all values of the sweep

ratio. Figure 37 presents the regions within the reactor that falls within the recommended flammability limits ( $O_2/CH_4$  ratio between 4.1 and 4.8) for three sweep ratios (15.67, 24.0, 49.0) considering the two cases of co-current and counter-current regimes. These recommended flammability limits correspond to stoichiometric oxygen to methane ratio up to 10 to 30% excess oxygen. The three considered sweep ratios are the ones that guarantee mixtures within the flammability limits. However, as shown in the figure only the mixture having sweep ratio of around 24 for the co-current flow and around 15.67 for the counter-current flow lie within the recommended mixture composition. Other sweep ratios show either rich or lean mixtures. The figure also confirms that the counter-current flow requires less sweep ratio for achieving the recommended  $O_2/CH_4$  ratio because of the higher  $O_2$  permeation flux. It should be noted here that achieving a nearly uniform mixture composition along the membrane leads to nearly homogeneous reaction rates that are likely to result in achieving constant temperature along the membrane. This is essential for avoiding any thermal stresses along the membrane surface and achieving membrane stability.

Figure 38 Variation of the oxygen permeation flux along the membrane surface for different sweep ratios ( $\text{CO}_2/\text{CH}_4$ ), (○ △ □ ◇) co-current regime and (● ▲ ■ ◆) counter-current regime

The variation of the oxygen permeation flux along the membrane surface for the co-current and counter-current regimes are plotted in Figure 38 for different compositions of the sweep gas. The figure indicates that the O<sub>2</sub> permeation rate decreases along the length and reaches  $5.97 \times 10^{-06}$  (mol/m<sup>2</sup>/s) at exit for 100% CH<sub>4</sub> at the inlet for counter-current flow as compared to  $3.26 \times 10^{-07}$  (mol/m<sup>2</sup>/s) at exit for co-current. In general, the oxygen flux through the membrane surface in the counter-current regime has higher values as compared with the co-current case. In both regimes, the total O<sub>2</sub> permeation rate decreases with the increase of CO<sub>2</sub> in the sweep gas mixture and the same phenomenon was reported by [90] and [41]. In another study by [91], the decrease of O<sub>2</sub> permeation due to the increase of CO<sub>2</sub> in the sweep gas was attributed to the formation of carbonates on the membrane surface which reduces oxygen permeation at high temperature. Figure 39 shows a comparison between the total O<sub>2</sub> permeation rate in the co-current and counter-current regimes. The obtained results indicate that the total O<sub>2</sub> permeation rate is always higher in the counter-current regime for all sweep gas compositions. As the percentage of CH<sub>4</sub> in the sweep gas changes from 100% to 10%, the counter-current regime results in permeation rates that are 6.62% to 12.75% higher than those of the co-current regime. Manccini and Mitsos [83,84] have developed a block box model for modelling an ITM reactor and got similar results which show that the counter-current regime is more viable than the co-current.

Figure 39 Variation of total oxygen permeation rate with percentage of  $\text{CH}_4$  in the sweep mixture

## 5.2 Combustion in ITM Reactor

Ion Transport Membranes made in monolith honeycomb reactor can play an important role in combustion chamber for gas turbines used in power generation where methane is the main reactant [92]. This honeycomb reactor contains hundreds of parallel tubes of ITMs that are of the order of 2-4 mm in diameter. The oxygen that comes from the ITM reacts with methane and combustion takes place. In this section, the investigation has been extended to include from mixing of  $\text{CH}_4$  and  $\text{CO}_2$  with  $\text{O}_2$  to create combustion with single-step chemistry. At present the model can be assumed as a single ITM tube of monolith honeycomb reactor as shown in Figure 40, the wall of the reactor is assumed to be adiabatic [58,92] to ensure similarity with the experimental model for permeation done by Wang et al[58]. Bouyancy and the heat flux by radiation are neglected because of the small diameter of ITM reactor that leads to high convective heat transfer coefficients, implying that the difference of membrane temperature and free stream is small. The flow considered is laminar and steady in nature. It is also assumed that combustion doesn't affect oxygen permeation flux equation. By considering the same boundary conditions for the case of mixing, single-step chemistry for methane combustion is activated to see the viability of ITM reactor.

Figure 40. The cross section of the monolith reactor [92]

Table 4 List of model parameter values

Parameter	Value
$\dot{m}_{\text{inlet,permeate}}$	$1.625 \times 10^{-7} \text{ Kg/s}$
$\dot{m}_{\text{inlet,feed}}$	$5.85 \times 10^{-6} \text{ Kg/s}$
$T_{\text{inlet,permeate}}$	1073 K
$T_{\text{inlet,feed}}$	1073 K
$(Y_{\text{CH}_4}; Y_{\text{CO}_2})_{\text{permeate}}$	0.33 ; 0.67
$(Y_{\text{O}_2}; Y_{\text{N}_2})_{\text{air}}$	0.23 ; 0.77
$\rho_{\text{membrane}}$	3000 Kg/m <sup>3</sup>
$\lambda_{\text{membrane}}$	20 W/m/K [96]

A reactive ITM combines the separation of oxygen from air and oxidation of methane in order to reduce the overall size of the reactor and number of equipments in cycle. The chemical reaction at the permeate side produces high partial pressure difference along the membrane which in turn increases the oxygen permeation flux significantly. If the fuel combustion kinetics are significantly faster than the rate at which oxygen is getting permeated through the ITM membrane, the partial pressure of oxygen at permeate side will be very low that significantly enhances oxygen flux. To study the ITM

characteristics and combustion characteristics the numerical simulations are carried out with the conditions shown in table 4. Thermal conductivity of perovskite membranes such as LSCF, BaCeO<sub>3</sub>, BaZrO<sub>3</sub> ranges from 5-12 W/m/K for temperature operation in the range 500-1000 °C [93,94, 95]. The thermal conductivity is still unknown for BSCF and the analysis done by Kaisare and Vlachos [96] suggested that for ceramic membrane the thermal conductivity is very low and varies from 3 to 100 W/m/K. In the present simulation the thermal conductivity of BSCF is assumed 20 W/m/K.

Figure 41 Temperature, reaction rate and composition profiles

Figure 41 (a) shows the temperature and kinetic rate of reaction for the simulations conditions shown in table 5. The axial temperature within the reactor increases along with the rate of reaction and reaches a maximum of 1249.5 K then rate of reaction drops as the methane is getting consumed. Figure 41 (b) shows the composition profiles which indicates clearly where the fuel is consumed, and the mass fraction of O<sub>2</sub> increases downstream significantly. The mass fraction of O<sub>2</sub> first increases very fast then decreases till the methane is consumed, this is due to fast consumption of fuel. For the given fuel

mass fraction and mass flow rate in table 4, the amount of  $O_2$  permeated through the membrane is  $8.68 \times 10^{-6}$  mol/s for the surface area of  $12.56 \text{ cm}^2$  which constitutes of  $O_2/CH_4$  of 5.178.

Figure 42 Oxygen permeation Flux for the reactive and separation only case.

Figure 42 shows the  $O_2$  permeation flux ( $J_{O_2}$ ) for the same case considering reactive and separation-only modes. From the figure, it is clear that for the reactive case, the  $O_2$  permeation flux decreases till the reaction starts then increases till the rate of reaction is maximum and then decreases gradually till fuel is totally consumed. It is evident from the figure that with the reaction mode at the permeate side, the  $O_2$  permeation flux is very high compared to separation-only mode due to the high partial pressure difference of  $O_2$  created across the membrane by chemical reaction. It gives conclusive remark that with chemical reaction for a particular membrane surface, the amount of  $O_2$  permeated is

higher compare to separation-only mode; thereby the length of the ITM reactor can be greatly reduced.

In order to study temperature and reaction kinetics for different sweep mixture compositions a parametric study is carried for the conditions shown in table 5.

Figure 43 Temperature profiles for the different sweep gas mixture for three different mass flow rates.

### 5.2.1 Temperature characteristics:

The axial temperature profiles within the reactor for different sweep gas mixture composition are shown in Figure 43. For the low mass flow rate of  $1.625 \times 10^{-7}$  Kg/s at the inlet the temperature rises quickly to 1250 K at  $1/5^{\text{th}}$  of the length from inlet of the reactor and then downstream. This drop is due to the cooling of the flue gases by permeating  $\text{O}_2$  from the membrane. When the mixture composition of  $\text{CH}_4/\text{CO}_2$  (mass ratio  $m_R$ ) increases beyond 0.4/0.6, the exit temperature of the reactor becomes almost constant at about 1222 K. Figure 43 (b) shows the temperature profile for the mass flow rate of  $4.625 \times 10^{-7}$  Kg/s for the same composition mixtures mentioned in table 5. From the figure, it is evident that the maximum temperature reaches 1310 K for almost all the mass ratios  $m_R$  and the exit temperature is about 1220 K except for the first two cases of mass ratio  $m_R$  of 0.1/0.9 and 0.12/0.88. This is mainly because the fuel is completely consumed within the reactor and the incoming  $\text{O}_2$  lower the exit temperature to 1142 K for the case with the mass ratio  $m_R$  of 0.12/0.88. Figure 43 (c) shows the temperature profile for the mass flow rate of  $8.625 \times 10^{-7}$  Kg/s where the maximum temperature drops from 1411 K to 1334 K for the composition  $\text{CH}_4/\text{CO}_2$  mass ratio of 0.06/0.94 to 1.0/0. Unlike the cases of mass flow rate of  $1.625 \times 10^{-7}$  Kg/s and  $4.625 \times 10^{-7}$  Kg/s, the exit temperature in the present case varies for the from 1214 K to 1297 K composition mass ratio  $m_R$  of 0.1/0.9 to 1.0/0 except for 0.06/0.94 is 1149 K and this is due to the complete combustion before the exit of the reactor and it can be clearly explained by the rate of reaction profiles.

Figure 44 shows the rate of reaction profiles for the aforementioned mass flow rates of  $1.625 \times 10^{-07}$  Kg/s,  $4.625 \times 10^{-07}$  Kg/s and  $8.625 \times 10^{-07}$  Kg/s. In figure 44 (a), it is shown that the rate of reaction reaches to nearly  $0.0062 \text{ Kg-mol/m}^3\text{-s}$  and drops along the length of the reactor. For the composition  $\text{CH}_4/\text{CO}_2$  mass ratio  $m_R$  of 0.1/0.9 to 0.3/0.7 the rate of reaction becomes zero within the reactor and for  $m_R = 0.33/0.67$  the rate of reaction becomes zero at exit of the reactor and this is due to the fact the fuel is totally consumed. It is noted that temperatures and rate of reaction profiles for the  $m_R$  ranging from 0.5/0.5 to 1.0/0 is almost the same leaving some unburned fuel at the exit with high temperatures. If the reactor is designed to follow uniform temperature combustion process more closely, then the temperature related problems could be significantly mitigated. So, the composition  $m_R = 0.5/0.5$  to 1.0/0 could be used and the ITM reactor could be split into a series of units where the exhaust of the first reactor unit is feed in second and so on till the fuel is totally consumed. With increase of mass flow rate from  $1.625 \times 10^{-07}$  Kg/s to  $4.625 \times 10^{-07}$  Kg/s the maximum value of rate of reaction increased to  $0.00108 \text{ Kg-mol/m}^3\text{-s}$  and the reaction started earlier at the left side of the reactor. This is due to the fact the rate of  $\text{O}_2$  permeation is same but the velocity of fuel is increased and hence it takes time to start the reaction kinetics.

Figure 44 Kinetic rate of reaction profiles for different sweep gas mixture for three different mass flow rates.

Figure 44 (c) shows the reaction rate profiles for the mass flow rate of  $8.625 \times 10^{-7}$  Kg/s. It can be seen that the magnitude of maximum reaction rate decreases as we increase  $m_R$  and the start of the reaction shifts to almost middle of the reactor, this is due to the fact the  $O_2/CH_4$  value decreases along the length of the reactor and can be seen in Figure 45. It is clear from the figure that for high mass flow rate, the increase of  $CH_4$  content reduces the reaction kinetics and the  $CH_4$  conversion percentage gets reduced. From the above discussion, it can be concluded that with less diluent  $CO_2$  at inlet high maximum temperatures can be achieved for increasing mass flow rate. This is accompanied by a reduction in conversion percentage of  $CH_4$ . With split ITM reactor design, the problem of fuel conversion can be overcome with uniform temperature along the reactor.

Figure 45  $O_2/CH_4$  profiles for the different sweep gas composition

### 5.2.2 Combustion characteristics:

For the optimal design of ITM reactor which combines O<sub>2</sub> separation and fuel oxidation, the amount of CH<sub>4</sub> conversion is an important parameter that is affected by the diluent CO<sub>2</sub> concentration and O<sub>2</sub> permeation flux. Figure 46 shows the CH<sub>4</sub> mass fraction profiles for different CH<sub>4</sub>/CO<sub>2</sub> m<sub>R</sub> compositions for increasing mass flow rates. It is evident that the conversion of CH<sub>4</sub> to combustible products decreases with the increase of CH<sub>4</sub> percentage at the inlet. For more diluent of CO<sub>2</sub> at higher mass flow rate at inlet, the maximum temperature is reached but the exit temperature for all the simulations ranges from 1148 K to 1297 K. In order to increase the O<sub>2</sub> permeation flux from ITM there must be sufficient methane input so that the chemical reaction doesn't stop at the first part of the reactor. For m<sub>R</sub> in the range 0.1/0.9 to 0.3/0.7 for mass flow rate of  $1.625 \times 10^{-07}$  Kg/s all the CH<sub>4</sub> is consumed and the permeating O<sub>2</sub> downstream cools the flue gases resulting in a decrease in the temperature. As discussed earlier, for the case of m<sub>R</sub> of 0.33/0.67 in figure 41, the reaction ends near the exit of the reactor and  $\Delta T$  is not much less compared to the lower percentage of CH<sub>4</sub> at inlet. For m<sub>R</sub> > 0.33/0.67 in feed for mass flow rate of  $1.625 \times 10^{-07}$  Kg/s, the CH<sub>4</sub> conversion reduced to 36.8% for m<sub>R</sub> = 1.0/0 can be seen in figure 47. For the mass flow rate of  $4.625 \times 10^{-07}$  Kg/s 100% CH<sub>4</sub> conversion is obtained for m<sub>R</sub> = 0.12/0.88 or less and CH<sub>4</sub> conversion is greatly reduced to 13.5% for m<sub>R</sub> = 1.0/0. The mass flow rate of  $8.625 \times 10^{-07}$  Kg/s yields to 7.5% CH<sub>4</sub> conversion for m<sub>R</sub> = 1.0/0 and 100% CH<sub>4</sub> conversion at very low m<sub>R</sub> = 0.06/0.94 or less. On the whole, the amount of CH<sub>4</sub> burned does not vary much since it depends on the O<sub>2</sub> available for combustion. In order to get to burn more amount of CH<sub>4</sub>, the surface area of the

membrane must be increased in such a way that the surface to volume ratio of the reactor must be high. Figure 46(b) and (c) depicts that the consumption of CH<sub>4</sub> is delayed due to the increase of the flow velocity and hence the length to attain O<sub>2</sub>-CH<sub>4</sub> in flammability limit is increased. In order to maintain a uniform temperature within the reactor, the maximum methane percentage is required, from the three mass flow rates presented  $1.625 \times 10^{-07}$  Kg/s,  $4.625 \times 10^{-07}$  Kg/s, and  $8.625 \times 10^{-07}$  Kg/s, the lowest giving the uniform temperature with the composition of m<sub>R</sub> above 0.5/0.5.

Figure 48 show the percentage of CH<sub>4</sub> and O<sub>2</sub> conversion for increasing percentage of CH<sub>4</sub> at the inlet. It is evident from the figure, that upto 33% of CH<sub>4</sub> at inlet with flow rate of  $1.625 \times 10^{-07}$  Kg/s the CH<sub>4</sub> conversion is 100%. O<sub>2</sub> conversion increases till 40% CH<sub>4</sub> and becomes constant with 93% conversion. Figure also represents the O<sub>2</sub> permeation rate which becomes constant above 33% CH<sub>4</sub> at inlet to a value of  $9.33 \times 10^{-06}$  mol/s, similar profile for O<sub>2</sub> permeation rate and conversion of CH<sub>4</sub> and O<sub>2</sub> is obtained by Tan et al [57] for LSCF-ITM membrane.

Figure 46 CH<sub>4</sub> Mass fraction profiles for different sweep gas composition

Figure 47 Percentage CH<sub>4</sub> conversion for different mass flow rates

Figure 48 Percentage of O<sub>2</sub> & CH<sub>4</sub> conversion and O<sub>2</sub> permeation rate for mass flow rate of  $1.625 \times 10^{-07}$  Kg/s

Figure 49 O<sub>2</sub>/CH<sub>4</sub> vs Percentage of CH<sub>4</sub> at inlet for different mass flow rates

O<sub>2</sub>/CH<sub>4</sub> value is an important parameter to decide the region of flammability limit for combustion. Figure 49 shows the representation of all the three mass flow rates with different CH<sub>4</sub>% at inlet. It can be seen that the only low mass flow rate of  $1.625 \times 10^{-07}$  Kg/s comes under lean region with 100% conversion of CH<sub>4</sub> with O<sub>2</sub>/CH<sub>4</sub> value of 5.178. This is because the combustion of CH<sub>4</sub> in ITM reactor is non-premixed and is highly dependent on mixing of species.

Figure 50 shows the  $O_2$  mass fraction for increasing  $CH_4\%$  concentration at inlet for three different mass flow rates. The  $O_2$  mass fractions are important since the mass fraction is related with mole fraction. Since the ITM reactor is operating at atmospheric pressure, the mole fraction is nothing but  $O_2$  partial pressure and permeation rate is highly dependent on that  $O_2$  partial pressure. Figure 50 and 51 are related since  $O_2$  permeation flux  $J_{O_2}$  is dependent on  $O_2$  partial pressure across the membrane. Since the  $O_2$  partial pressure at feed is fixed (0.21 atm) as per equation (36) then variation of  $J_{O_2}$  is more governed by  $O_2$  partial pressure at permeate side than temperature since the temperature rise within the reactor is nearly of the order of 200 K. The lesser the  $O_2$  partial pressure at the permeate side the higher the  $O_2$  permeation flux. Figure 50 (a) shows, that the  $O_2$  partial pressure is zero at inlet of the permeate side and hence the maximum  $O_2$  permeation flux. Along the length of the reactor  $O_2$  mass fraction increases till  $O_2$  is sufficient to burn  $CH_4$  then decreases till the reaction rate becomes maximum. For  $m_R$  of 0.1/0.9 the reaction is ended at  $X/L$  of 0.25 as the total  $CH_4$  is consumed and  $O_2$  mass fraction increases downstream while  $O_2$  permeation decreases till the exit of the reactor. For the  $m_R$  ranging from 0.2/0.8 to 0.33/0.67, the trend of  $O_2$  mass fraction follows as that of previous ratio except the magnitude increases and reaction zone increased. For higher  $m_R > 0.33/0.67$ , the  $O_2$  mass fraction is almost constant leading to almost constant  $O_2$  permeation flux as shown in Figure 51 (a). For the increased mass flow rates at inlet of  $4.625 \times 10^{-07}$  Kg/s and  $8.625 \times 10^{-07}$  Kg/s the maximum value of  $O_2$  mass fraction is almost the same but the peak is shifted from  $X/L$  of 0.25 to 0.6. This is attributed to the shift in the rate of reaction as can be seen in figure 34. At the higher mass flow rate of

$8.625 \times 10^{-07}$  Kg/s, the  $O_2$  permeation flux decreases till X/L of 0.7 for  $m_R = 1.0/0$ . From the above discussion, it is depicted that for an ideal ITM reactor the mass flow rate of  $1.625 \times 10^{-07}$  Kg/s with composition  $m_R$  of above 0.5/0.5 to 1.0/0 is suitable for uniform temperature operations. This results in maximum  $O_2$  permeation flux with 75%  $CH_4$  conversion for  $m_R = 0.5/0.5$  to 37% for  $m_R = 1.0/0$ . A simple analysis of Figures 38 and 51 (a) shows that the oxygen permeation flux through this type of membranes is more sensitive to the changes in  $O_2$  partial pressure in the reaction side. For the case without reaction (separation-only), oxygen permeate does not react with the sweep gases ( $CH_4 + CO_2$ ). Therefore,  $O_2$  partial pressure at permeate side ( $P_2$ ) is much larger in the case of non-reacting medium. As a result, the driving force  $[(P_1)^{1/2} - (P_2)^{1/2}]^{0.623}$  is lower than that in the case of combustion.

Figure 50 O<sub>2</sub> Mass Fraction Profiles for different sweep gas composition

Figure 51 O<sub>2</sub> Permeation flux for different sweep gas composition

Figure 52 Radial temperature profiles at different sections for mass low rate of

$$1.625 \times 10^{-07} \text{ Kg/s}$$

Figure 52 shows the radial temperature profiles at different sections ( $X/L = 0.15, 0.25, 0.5$  and at  $1.0$ ) for the mass flow rate of  $1.625 \times 10^{-07}$  Kg/s. At  $X/L=0.15$ , the reaction is just started and the temperature start rising and at  $X/L=0.25$  the reaction rates are maximum for almost all composition mixtures. At  $X/L=0.5$  the temperature is dropped

for low CH<sub>4</sub> mixture composition due to the depletion of CH<sub>4</sub>. The temperature dropped for m<sub>R</sub> less than 0.5/0.5 at exit due drop of high CH<sub>4</sub> conversion.

Figure 53 shows the radial profiles of O<sub>2</sub> mass fraction for a mass flow rate of  $1.625 \times 10^{-7}$  Kg/s for three different m<sub>R</sub> of 0.1/0.9, 0.5/0.5 and 1.0/0 at four different sections (X/L=0.15, 0.25, 0.5, 1.0). It can be seen that at X/L =0.15 the O<sub>2</sub> mass fraction at feed side drops significantly from 0.225 to 0.218 radially from outer wall of the shell to the membrane surface. At this section O<sub>2</sub> mass fraction at permeate of m<sub>R</sub>= 0.1/0 is very low compare to m<sub>R</sub>= 0.5/0.5 and 1.0/0 due to early reaction initiation. At section X/L =0.25 the reaction rate of m<sub>R</sub>= 0.5/0.5 is maximum compare to other m<sub>R</sub> considered. It can be seen that the variation of O<sub>2</sub> mass fraction radially is maximum in this section which gives maximum temperature. From the section X/L =0.5 and 1.0, it is clear that the CH<sub>4</sub> is totally consumed for m<sub>R</sub> = 0.1/0.9 and there is no much variation of O<sub>2</sub> mass fraction radially. For m<sub>R</sub> = 0.1/0.9 and 1.0/0 there is no much difference in magnitude of O<sub>2</sub> mass fraction and it can be radial temperature profiles (Figure 52) that there is no much difference in their magnitude this is due to O<sub>2</sub> permeation flux becomes constant after m<sub>R</sub> =0.33/0.67 which can be seen in figure 48. Figure 54 shows the temperature and composition profiles in radial direction for m<sub>R</sub> =0.5/0.5 for mass flow rate of  $1.625 \times 10^{-7}$  Kg/s at different sections (X/L=0.15, 0.25, 0.5, 1.0). It can be seen that the maximum temperature and maximum  $\Delta T$  along the radial direction is achieved at X/L=0.25, 0.5 and  $\Delta T_{\max}$  is 40 K.

Figure 53 O<sub>2</sub> mass fraction radial profiles for mass flow rate of  $1.625 \times 10^{-7}$  Kg/s

Figure 54 Radial temperature and composition profiles for mass flow rate of  $1.625 \times 10^{-7}$  Kg/s for  $m_R$  of 0.5/0.5

Figure 55 shows the temperature, composition profiles for one  $m_R$  of 0.5/0.5 for increasing mass flow rates. It can be seen from the figure that the difference in axial temperature and membrane temperature is around 30 K only. For the low mass flow rate  $\text{CH}_4$  conversion achieved is highest and the uniform temperature is achieved where the  $\text{O}_2$  mass fraction is lowest. After  $X/L=0.25$  the temperature drops and it is attributed to the decrease in the reaction rate because of increasing value of  $\text{O}_2/\text{CH}_4$ . For mass flow

rate of  $1.625 \times 10^{-7}$  Kg/s the maximum temperature is increased to 1310 K but the reaction zone is shifted and reaction is delayed to achieve  $O_2/CH_4$  ratio for combustion. The same phenomenon is observed for high mass flow rate of  $8.625 \times 10^{-7}$  Kg/s and the conversion of  $CH_4$  is reduced significantly. This data gives information in designing OTR to maintain uniform temperature as well as the amount of  $CH_4$  that can be burnt for a particular surface area membrane reactor.

Figure 55 Temperature and composition profiles for three different mass flow rates at  $m_R = 0.5/0.5$

### 5.2.3 Effect of fuel mass flow rate on O<sub>2</sub> permeation flux (J<sub>O<sub>2</sub></sub>):

Figure 56 Effect of mass flow rate of fuel on the oxygen permeation flux

The mass flow rate of fuel (CH<sub>4</sub> and CO<sub>2</sub>) has a great effect the oxygen permeation flux through ITM. As shown in Figure 56, the increase in sweep gas mass flow rate tends to decrease the O<sub>2</sub> permeation flux for a prolonged distance. Furthermore, the reaction side O<sub>2</sub> partial pressure increases till the reaction starts and then drops and becomes constant for low mass flow rate because of the extinction of fuel.

#### 5.2.4 Effect of fuel mass flow rate on combustion temperature:

Figure 57 Temperature profiles for different fuel mass flow rates

Figure 57 presents the effect mass flow rate of fuel on the combustion temperature. The figure shows an increase of the combustion temperature with increasing sweep gas mass flow rate till a certain value and then starts to decrease except for mass flow rate of  $1.625 \times 10^{-7}$  Kg/s where the uniform temperature is maintained in more than 75% of the reactor. With increase of fuel mass flow rates, peak temperature increases and then drops but the condition of nearly isothermal operation can be achieved.

### 5.2.5 Effects of fuel mass flow rate on permeate O<sub>2</sub> partial pressure:

Figure 58 O<sub>2</sub> partial pressure profiles for different fuel mass flow rates

Figure 58 shows the change in oxygen partial pressure as a function of sweep gas mass flow rate for the case when combustion is activated at constant feed oxygen partial pressure of 0.21atm. As shown in the figure, the permeate O<sub>2</sub> partial pressure increases tending to lowering the O<sub>2</sub> permeation flux then when O<sub>2</sub>/CH<sub>4</sub> reaches the flammability limit, the O<sub>2</sub> partial pressure drops leading to increase in O<sub>2</sub> permeation flux. This can be easily seen in Figures 50 and 51 which shows the O<sub>2</sub> mass fraction and O<sub>2</sub> permeation flux profiles for increasing sweep gas mass flow rate.

### 5.2.6 Effect of mass flow rate on O<sub>2</sub>/CH<sub>4</sub> ratio:

Figure 59 O<sub>2</sub>/CH<sub>4</sub> for different mass flow rates

Figure 59 shows the O<sub>2</sub>/CH<sub>4</sub> profiles for the different mass flow rate for the sweep gas composition m<sub>R</sub> of 1.0/0. With increase of mass flow rate, the O<sub>2</sub>/CH<sub>4</sub> ratio increases but the reaction zones shifts near to the exit of the reactor. The maximum temperature is achieved when the peak O<sub>2</sub>/CH<sub>4</sub> drops for all the three mass flow rates and can be seen in Figure 57. The closer the peak of O<sub>2</sub>/CH<sub>4</sub>, more will the reaction zone within OTR. It can be seen that for 1.625×10<sup>-07</sup> Kg/s the value of O<sub>2</sub>/CH<sub>4</sub> increases downstream making

reaction rate and temperature uniform in the OTR. From the above discussion it is concluded that more  $\text{CH}_4$  at low mass flow rate is favourable to have in the reactor.

Figure 60 Comparison between oxygen permeation rate from the ITM with and without combustion for mass flow rate of  $1.625 \times 10^{-7}$  Kg/s

Figure 60 shows the oxygen permeation rate in mol/s from the membrane for cold combustion (separation only) and combustion cases. In the figure abscissa is the percentage of  $\text{CH}_4$  in fuel mixture while the ordinate is the  $\text{O}_2$  permeation rate. The amount of oxygen coming through the membrane towards the permeate side for cold

combustion (mixing) is  $3.29 \times 10^{-6}$  mol/s to  $3.97 \times 10^{-6}$  mol/s while for combustion case it is  $4.11 \times 10^{-6}$  mol/s to  $9.33 \times 10^{-6}$  mol/s for 10% to 100% of CH<sub>4</sub> at inlet of fuel mixture. The oxygen permeation rate through the membrane is increases for 10% to 33% CH<sub>4</sub> at inlet and becomes almost constant for the increased CH<sub>4</sub> percentages. This is due to the complete combustion of CH<sub>4</sub> upto 33% at inlet. Oxygen permeation rate through ITM for combustion is very much higher compare with sweep mixture of cold mixing and it is 25% to 135% higher for 10% to 100% CH<sub>4</sub> at inlet.

### **5.2.7 Temperature contours for different compositions:**

Figure 61 shows the temperature contour of different CH<sub>4</sub>/CO<sub>2</sub> composition mass ratio  $m_R$  for mass flow rate of  $1.625 \times 10^{-07}$  Kg/s. Its can been seen that reaction starts at X/L of 0.15 for almost all the  $m_R$  with O<sub>2</sub> partial pressure at feed side  $P_1 = 0.21$  atm. As shown, the combustion zone has a maximum temperature of 1250°C. As the maximum temperature increases, the membrane temperature will also increase; however, part of this heat will be lost to the air domain through the membrane. One can also see from the figure that the temperature around the membrane is less compare to core of the reactor. This will extend the membrane working period and prevent membrane fracture due to thermal stresses on the membrane surface. However more research in required in the membrane materials in order to make it able to withstand higher temperatures with higher oxygen permeation flux. Similar contours can be seen in Figure 61 and 62 for increased mass flow rates. From Figure 61 it is clear that the maximum value of temperature is increased within the reactor but the reaction zone is shifted. For higher mass flow rate of

$8.625 \times 10^{-07}$  Kg/s the reaction zone is shifted to  $X/L = 0.5$ . In order to maintain the high  $O_2$  permeation flux the uniform temperature should be maintained for the whole reactor and with the high mass flow rate the uniform temperature ITM cannot be achieved.

Due to the high reactor temperature and small reactor geometry, the strain rate ( $dU/dx$ ) will be increased due to reduced density and so increased velocity for a particular mass flow rate. This will lead to higher maximum heat release rate in the reaction zone. The flame zone is in the middle of the reactor as shown in Figure 61, 62 and 63. Most of the heat released is lost to air side through the membrane because these membranes have very low thermal resistance.

In order to maximize the  $CH_4$  conversion at high mass flow rates use of catalyst on ITM at permeate side is suggested [92], before proceeding into the catalytic conversion of  $CH_4$  more work has to be done on material development and testing side.

From the above discussion, it is clear that ITM has potential to be implemented in the transforming a conventional combustion chamber to ITM reactor in which separation and oxidation of fuel is done simultaneously by which in turn improves the  $O_2$  separation.

Figure 61 Temperature contour for mass flow rate of  $1.625 \times 10^{-07}$  Kg/s and different  $\text{CH}_4/\text{CO}_2$  mixtures mass ratio  $m_R$

Figure 62 Temperature contour for mass flow rate of  $4.625 \times 10^{-07}$  Kg/s and different  $\text{CH}_4/\text{CO}_2$  mixtures mass ratio  $m_R$

Figure 63 Temperature contour for mass flow rate of  $8.625 \times 10^{-07}$  Kg/s and different

$\text{CH}_4/\text{CO}_2$  mixtures mass ratio  $m_R$

Figure 64 Temperature contour for three different mass flow rate of  $8.625 \times 10^{-7} \text{ Kg/s}$  for  $\text{CH}_4/\text{CO}_2$  of 1.0/0.

Figure 64 shows the temperature contours of three different mass flow rates for a  $m_R$  ( $\text{CH}_4/\text{CO}_2$ ) of 1.0/0. From the figure, it can depict that with increase of mass flow rate from  $1.625 \times 10^{-7} \text{ Kg/s}$  to  $8.625 \times 10^{-7} \text{ Kg/s}$ , the maximum temperature within the reactor is increased. The idea of designing a practical OTR is to maintain uniformity in the

temperature to reduce the thermal stresses that may occur with the variation of membrane temperature. So, the uniform temperature within the reactor can be obtained for low mass flow rate of  $1.625 \times 10^{-7}$  Kg/s but with 1250K maximum temperature.

### 5.3 Energy Balance verification

In order to verify the combustion within ITM reactor, energy balance is done for one particular case with the mass flow rate of  $1.625 \times 10^{-7}$  Kg/s with CH<sub>4</sub>/CO<sub>2</sub> of 0.3/0.7. Reactor operates as adiabatic.

Figure 65 Block Diagram of ITM reactor

In the inlet temperature  $T_{inlet} = 1073 \text{ K}$ ,  $T_r = 298.15 \text{ K}$

$T_{\text{outlet}} = 1091.4 \text{ K}$  obtained as mass weighted average temperature at outlet of fuel side from FLUENT  
 $T_{\text{Mem}} = 1084.1 \text{ K}$

Energy balance equation given below.

$$\begin{aligned}
 & \left( \dot{m}_{\text{CH}_4} \right)_{\text{f,inlet}} (\text{LCV} + C_{p_{\text{CH}_4}} (T_{\text{inlet}} - T_r)) + \left( \dot{m}_{\text{CO}_2} \right)_{\text{f,inlet}} C_{p_{\text{CO}_2}} (T_{\text{inlet}} - T_r) + \\
 & \left( \dot{m}_{\text{O}_2} \right)_{\text{air,inlet}} C_{p_{\text{O}_2}} (T_{\text{inlet}} - T_r) + \left( \dot{m}_{\text{N}_2} \right)_{\text{air,inlet}} C_{p_{\text{N}_2}} (T_{\text{inlet}} - T_r) \\
 & = \left( \dot{m}_{\text{CO}_2} \right)_{\text{f,outlet}} C_{p_{\text{CO}_2}} (T_{\text{f,outlet}} - T_r) + \left( \dot{m}_{\text{H}_2\text{O}} \right)_{\text{f,outlet}} C_{p_{\text{H}_2\text{O}}} (T_{\text{f,outlet}} - T_r) + \\
 & \left( \dot{m}_{\text{O}_2} \right)_{\text{f,outlet}} C_{p_{\text{O}_2}} (T_{\text{f,outlet}} - T_r) + \left( \dot{m}_{\text{N}_2} \right)_{\text{air,outlet}} C_{p_{\text{N}_2}} (T_{\text{air,outlet}} - T_r) + \\
 & \left( \dot{m}_{\text{O}_2} \right)_{\text{air,outlet}} C_{p_{\text{O}_2}} (T_{\text{air,outlet}} - T_r) + k_{\text{mem}} \oint_s \nabla T \, dA
 \end{aligned}$$

Energy entering C.V calculation:

$$\begin{aligned}
 \left( \dot{m}_{\text{CH}_4} \right)_{\text{f,inlet}} (\text{LCV} + C_{p_{\text{CH}_4}} (T_{\text{inlet}} - T_r)) &= 4.88 \times 10^{-8} (5.534 \times 10^7 + 8.99(1073 - 298.15)) \\
 &= 2.70034 \text{ W}
 \end{aligned}$$

$$\begin{aligned}
 \left( \dot{m}_{\text{CO}_2} \right)_{\text{f,inlet}} C_{p_{\text{CO}_2}} (T_{\text{inlet}} - T_r) &= 1.14 \times 10^{-7} \times 8.99 \times (1073 - 298.15) \\
 &= 5.86 \times 10^{-4} \text{ W}
 \end{aligned}$$

$$\begin{aligned}
 \left( \dot{m}_{\text{O}_2} \right)_{\text{air,inlet}} C_{p_{\text{O}_2}} (T_{\text{inlet}} - T_r) &= 1.35 \times 10^{-6} \times 4.2315 \times (1073 - 298.15) \\
 &= 4.43 \times 10^{-4} \text{ W}
 \end{aligned}$$

$$\begin{aligned}
 \left( \dot{m}_{\text{N}_2} \right)_{\text{air,inlet}} C_{p_{\text{N}_2}} (T_{\text{inlet}} - T_r) &= 4.5 \times 10^{-6} \times 3.985 \times (1073 - 298.15) \\
 &= 0.0139 \text{ W}
 \end{aligned}$$

$$\begin{aligned}\text{Energy\_in} &= 2.70034 + 5.86 \times 10^{-4} + 4.43 \times 10^{-4} + 0.0139 \\ &= 2.716 \text{ W}\end{aligned}$$

Energy leaving C.V calculation:

$$\begin{aligned}\left(\dot{m}_{\text{CO}_2}\right)_{\text{f,outlet}} \text{Cp}_{\text{CO}_2} (T_{\text{outlet}} - T_r) &= 2.695 \times 10^{-7} \times 6.645 \times (1091.5 - 298.15) \\ &= 1.421 \times 10^{-3} \text{ W}\end{aligned}$$

$$\begin{aligned}\left(\dot{m}_{\text{H}_2\text{O}}\right)_{\text{f,outlet}} \text{Cp}_{\text{H}_2\text{O}} (T_{\text{outlet}} - T_r) &= 1.19 \times 10^{-7} \times 5.123 \times (1091.5 - 298.15) \\ &= 4.84 \times 10^{-4} \text{ W}\end{aligned}$$

$$\begin{aligned}\left(\dot{m}_{\text{O}_2}\right)_{\text{f,outlet}} \text{Cp}_{\text{O}_2} (T_{\text{outlet}} - T_r) &= 5.05 \times 10^{-7} \times 0.1151 \times (1091.5 - 298.15) \\ &= 4.611 \times 10^{-5} \text{ W}\end{aligned}$$

$$\begin{aligned}\left(\dot{m}_{\text{N}_2}\right)_{\text{air,outlet}} \text{Cp}_{\text{N}_2} (T_{\text{air,outlet}} - T_r) &= 4.5 \times 10^{-6} \times 3.9896 \times (1081.6 - 298.15) \\ &= 0.01406 \text{ W}\end{aligned}$$

$$\begin{aligned}\left(\dot{m}_{\text{O}_2}\right)_{\text{air,outlet}} \text{Cp}_{\text{O}_2} (T_{\text{air,outlet}} - T_r) &= 1.078 \times 10^{-6} \times 4.235 \times (1081.6 - 298.15) \\ &= 3.577 \times 10^{-3} \text{ W}\end{aligned}$$

$$\begin{aligned}k_{\text{mem}} \oint_s \nabla T dA &= 20 \times 0.136 \\ &= 2.72 \text{ W}\end{aligned}$$

$$\begin{aligned}\text{Energy leaving C.V} &= 2.72 + 1.421 \times 10^{-3} + 4.84 \times 10^{-4} + 4.611 \times 10^{-5} + 0.01406 \\ &= 2.721 \text{ W}\end{aligned}$$

From the above analysis it is clear that energy is balanced and the combustion of ITM reactor gives affirmative results.

#### **5.4 Effect of local temperature variation along the membrane surface and radiation heat transfer on the combustion process**

In the previous analysis, the effects of ITM temperature variation along the membrane surface on the oxygen permeation rate and the radiation heat transfer were neglected. In order to assess the effect of both factors on the combustion process and the resulting thermal field, we conduct detailed computational analysis of three cases. These include the mass flow rate of  $1.625 \times 10^{-7}$  Kg/s and mass ratios  $m_R=0.1/0.9$ ,  $0.5/0.5$  and  $1.0/0$ . In all cases, the inlet air and sweep gas temperatures are assumed unchanged (1073K). Both compartments are assumed to have atmospheric pressure.

In the previous calculations, the  $O_2$  permeation flux was based on equation (36) in which the coefficient  $K_2(T)$  was assumed constant (corresponding to inlet temperature) along the membrane surface. Since the  $O_2$  permeation flux depends on the local partial pressures of  $O_2$  on both sides of the membrane as well as the local membrane temperature, we must develop a new correlation that takes the membrane temperature variation into consideration. The experimental data of Wang et al. [58] that are shown in Figure 66 forms the basis for obtaining this correlation. The least square method was used for fitting the data (for different temperature ranging from 700 °C to 900 °C and different partial pressures) assuming an exponential relation between  $K_2(T)$  and the

temperature. Equation (37) is the obtained correlation that gives the best fit to all data points.

$$J_{O_2} = 0.2609K_1 \exp\left(-\frac{4270}{T}\right) \left( \sqrt{\frac{P_1}{P_0}} - \sqrt{\frac{P_2}{P_0}} \right) \quad (37)$$

$$K_1 = \frac{2\pi r_1 r_2 w}{S(r_1 + r_2)}$$

Figure 66 Oxygen Permeation flux through the BSCF membrane tube as a function of temperature [58].

Figure 67 represents the  $O_2$  permeation flux for different partial pressure of  $O_2$  at shell side for increasing temperatures. A simple comparison between the model prediction and the measured values of  $O_2$  permeation flux shows a reasonable accuracy. The largest

deviation was about 15% occurring at 900 °C and 0.2 atm. This deviation may be attributed to experimental uncertainties at high temperatures.

Figure 67 O<sub>2</sub> permeation flux for different temperature for increasing partial pressure at shell side.

In the present simulations, Discrete Ordinate (DO) radiation model is activated and the absorption coefficient was estimated by Weighted Sum of Gray Gas Model (WSGGM). Figure 68 (a) shows the temperature along the axis of the reactor for mass flow rate of  $1.625 \times 10^{-7}$  Kg/s for  $m_R=0.1/0.9$  considering the new O<sub>2</sub> permeation flux equation (37) and the radiation heat transfer model. The figure shows that the maximum temperature is increased by an amount of 25K when the local temperature effect is considered in the O<sub>2</sub>

permeation equation. Figure 68 (b) shows the temperature variation along the reactor axis for the same flow rate but with a mass ratio  $m_R=0.5/0.5$ .

Figure 68 Temperature along the axis of the reactor for mass flow rate of  $1.625 \times 10^{-7} \text{ Kg/s}$

for a)  $m_R=0.1/0.9$  b)  $m_R=0.5/0.5$  c)  $m_R=1.0/0$

The figure indicates a maximum temperature of 1143 K when the effect of the local temperature variation on the  $O_2$  permeation flux is considered compared with a maximum temperature of 1102 K when neglecting that effect.

For the case of pure CH<sub>4</sub> at inlet ( $m_R = 1.0/0$ ), Figure 68(c) shows small temperature variations along the reactor axis for both cases. The maximum temperature difference between the two cases of using the permeation equations (36) and (37) is about 16K.

Figure 69 Temperature contours for mass flow rate of  $1.625 \times 10^{-7} \text{ Kg/s}$  and  $m_R = 1.0/0$  with equation 36 and equation 37

Figure 69 shows the temperature contours for the same flow rate ( $1.625 \times 10^{-7} \text{ Kg/s}$ ) and for the mass ratio,  $m_R = 1.0/0$ , considering the two permeation equations (36) and (37). It can be noted that with equation (37) the maximum temperature is achieved at approximately  $X/L = 0.25$  while the maximum temperature is achieved at approximately

$X/L=0.5$  when using equation (36). The delay in the combustion process when using equation (36) is mainly due to the low rate of  $O_2$  permeation at the inlet region. Based on above analysis, it is clear that the effect of radiation as well as the effect of local temperature variation on the  $O_2$  permeation flux should be considered. However, we wished to have some experimental results to verify the accuracy of the computational model. The absence of this verification prevented fine tuning of the model. A number of questions and uncertainties are still not answered/clarified including the following:

1. The exact chemical reaction taking place (not fully known) will in turn affect the emission and absorption coefficients.
2. The detailed chemistry will definitely differ from the assumed one step chemical reaction and this will affect the chemical composition of combustion products.
3. The effect of composition of combustion products on  $O_2$  permeation through ITM is hard to assess because of lack of experimental results.
4. The  $O_2$  permeation equation needs further improvement by considering the mechanism of  $O_2$  ion exchange through the membrane based on the local parameters (temperature and partial pressures) and membrane characteristics. The obtained correlation [Eq. (37)] gives a maximum difference of 15% with the experimental results.

## **CHAPTER 6**

### **CONCLUSION AND**

### **RECOMMENDATIONS FOR FUTURE**

### **WORK**

The conclusion is divided into three sections. In the first two sections, the results in the previous chapter are summarized. In the last section, proposed directions for future research are presented.

#### **6.1 Cold Combustion (O<sub>2</sub> separation-only)**

A computational model is developed for predicting the performance of a cylindrical ion transport reactor designed for oxy-fuel combustion. The oxygen is supplied through the reactor walls which are made of dense, nonporous, mixed-conducting ceramic membrane that only allows oxygen permeation from the outside air into the combustion chamber. The details of the flow process and the concentration of different species are predicted by a numerical solution of the conservation equations of mass, momentum, energy and species in the axi-symmetric flow domain. The membrane is modelled as a selective layer in which the oxygen permeation depends on the prevailing temperatures as well as the

oxygen partial pressure at both sides of the membrane. The model results were validated against previous experimental data and the comparison showed a good agreement. The results indicated that the oxygen to fuel mass ratio increases as the percentage of  $\text{CO}_2$  increases in the inflow sweep gas for both co-current and counter-current regimes. In both regimes, the ratio of oxygen to methane increases for decreasing percentage of  $\text{CH}_4$  at inlet of the sweep side. It is also found that the increase in the sweep ratio tends to reduce the size of the region outside the flammability limits. The results also indicated that the counter-flow regime exhibits better mixing of fuel and oxygen and provides more uniform oxygen flux along the reactor wall. The total  $\text{O}_2$  permeation rate is found to be higher in the counter-current regime for all sweep gas compositions. The regions within the reactor that falls within the recommended flammability limits ( $\text{O}_2/\text{CH}_4$  ratio between 3.4 and 4.4) are investigated considering three sweep ratios (15.67, 24.0, 49.0). The results indicated that the mixtures having sweep ratio of around 24 for the co-current flow and around 15.67 for the counter-current flow lie within the recommended mixture composition. In both cases, the nearly uniform mixture composition along the membrane leads to nearly homogeneous reaction rates that are likely to result in achieving constant temperature over the membrane surface.

## **6.2 Combustion in Oxygen Transport Reactor (OTR)**

The results of combustion in OTR for different composition of  $\text{CH}_4/\text{CO}_2$  mixtures and for different mass flow rates have provided many important insights and conclusions. First, the comparison between reactive and separation-only OTR units showed that combining

reaction and separation increases significantly  $O_2$  permeation rate to about 2.5 times under the assumptions given herein. Second, for mass flow rate of  $1.625 \times 10^{-07}$  Kg/s with  $CH_4/CO_2$  mass ratio ranging from 0.5/0.5 to 1.0/0 gives almost uniform axial temperature of about 1250 K in most of the reactor length with high  $CH_4$  conversion of 75% to 35% respectively. In all the simulations, the total  $O_2$  permeation flux is almost the same except for  $1.625 \times 10^{-07}$  Kg/s with  $CH_4/CO_2$   $m_R$  less than 0.3/0.7. Since the thermal resistance of these membranes is low, the heat of reaction is mostly transferred to the air side with a portion used to heat the  $O_2$  permeating flux. For higher mass flow rates, the OTR operates with rich mixture resulting in low  $CH_4$  conversion. The combustion process in such cases can be improved by splitting the OTR into a series of units where the fuel is added at stages along the reactor network. This work requires significant experimental and modeling work and is outside the scope of this thesis.

### **6.3 Future work:**

The use of ITM technology to capture  $CO_2$  in power cycles shows potential to retrofit or to use as an auxiliary system to separate  $O_2$  for oxy-combustion. The  $O_2$  permeation equation used this work is based on experimental correlations. More work is needed to develop a more generalized equation which represents the membrane characteristics and operational conditions. Further, single-step chemistry is used in the present simulations for oxidation of methane into  $CO_2$  and  $H_2O$ , but in practice there will be other species such as  $CO$ ,  $H_2$ , etc. Accordingly, detailed chemistry must be employed to study the impact and stability of such species on ITM. Other major issues related to the effect of

carbon deposition and soot formation on the membrane characteristics need detailed investigation.

A single ITM reactor results in low exit temperature and much loss of heat into the air side, a series of ITM reactors could be created such that the membrane surface area is split to a series of segments. This may lead to a higher temperature at the reactor exit that makes the combustion products more suitable in power cycles.

## Nomenclature

$L_c$  characteristic membrane thickness [m]

$D_s$  self-diffusivity [ $m^2/s$ ]

$k_{io}$  surface exchange coefficient [m/s]

$t_i$  ionic transference number [ - ]

$t_e$  electronic transference number [ - ]

$\mu_{O_2}$  Oxygen vacancy potential [J/mol]

$L$  Membrane thickness [m]

$F$  Faraday's constant [c/mol]

$J_{O_2}$	oxygen permeation flux [mol/m <sup>2</sup> -s]
$\sigma_i$	ionic conductivity [S/m]
$\sigma_e$	electronic conductivity [S/m]
$R$	Gas constant [J/molK]
$p$	pressure [Pa]
$V_o^{\bullet\bullet}$	oxygen vacancy [ - ]
$D_v$	diffusion coefficient of oxygen vacancies [cm <sup>2</sup> /s]
$V_m$	molar volume [m <sup>3</sup> /mol]
$E_a$	activation energy [ J/kg-mol ]
$P_{O_2}', P_1$	partial pressure of oxygen at the feed side [atm]
$P_{O_2}'', P_2$	partial pressure of oxygen at the permeate side [atm]
$C_i$	density of oxygen ions [mol/m <sup>3</sup> ]
$T$	temperature [K]
$r_1$	outer radius of the membrane tube [m]
$r_2$	inner radius of the membrane tube [m]

$S$	effective area of the membrane tube [ $\text{m}^2$ ]
$\beta_1$	bulk-diffusion step constant [ - ]
$P_{O_2}^0, P_0$	1 atm oxygen pressure
$U$	velocity vector [ $\text{m s}^{-1}$ ]
$\rho$	density [ $\text{Kg m}^{-3}$ ]
$\mu$	dynamic viscosity [ $\text{N s m}^{-2}$ ]
$S_i$	source/sink term [ $\text{Kg/m}^3\text{-s}$ ]
$R_1$	resistance to $O_2$ permeation at the inner membrane surface [ $\text{atm}^{0.5}\text{cm}^2\text{sec/mol}$ ]
$R_2$	resistance to $O_2$ permeation in the bulk region [ $\text{atm}^{0.5}\text{cm}^2\text{sec/mol}$ ]
$R_3$	resistance to $O_2$ permeation at the outer membrane surface [ $\text{atm}^{0.5}\text{cm}^2\text{sec/mol}$ ]
$D_{i,m}$	diffusion coefficient of mixture of species i [ $\text{m}^2/\text{s}$ ]
$k_f$	surface-exchange reaction forward-rate constant [ $\text{cm atm}^{-0.5}\text{s}^{-1}$ ]
$k_r$	surface-exchange reaction reverse-rate constant [ $\text{mol cm}^{-2}\text{s}^{-1}$ ]
$K_1$	geometric constant [ - ]

$Y_i$	mass fraction of species i [ - ]
$D_{i,j}$	binary mass diffusion coefficient of species i [ $m^2/s$ ]
$C_p$	heat capacity [J/Kg-K]
$A_{cell}$	area of the cell [ $m^2$ ]
$MW_{O_2}$	molecular weight of oxygen [Kg/Kmol]
$V_{cell}$	volume of cell [ $m^3$ ]
$X_i$	mole fraction of species i [ - ]
$K_2$	constant depends on temperature [ $mol/m^2-s$ ]
$w$	effective length of the tube [m]
$\mathfrak{R}$	Universal gas constant [J/molK ]
$M_i$	molecular weight of species i [Kg/Kmol]
$\lambda_i$	thermal conductivity of species i [W/m/K]
$\phi_{i,j}$	mixture rule constant for species i in species j [ - ]
$k$	reaction rate constant [ Kg-mol/ $m^3-s$ ]
$A$	pre-exponential factor [ - ]
$\dot{m}$	mass flow rate [Kg/s]

**Suffix**

op            operating

mix           mixture

## **Vita**

Name: Azharuddin

Nationality: Indian

Present address: P.O. Box: 8620, KFUPM, Kingdom of Saudi Arabia.

Telephone: 00966552542328 (Present), 0091-9848931084 (Permanent)

Education: Received Bachelor of Engineering degree in Mechanical Engineering from Osmania University, Hyderabad, India in 2008

Experience: Worked as Field Operation and Panel Engineer in Reliance Industries Limited, India from 2008-2009.

Joined Mechanical Engineering Department of King Fahd University of Petroleum and Minerals, Dhahran as Research Assistant in October 2009.
